BACK HOME

THORAZINE®

brand of

CHLORPROMAZINE

Tablets:
50 and 100 mg
of the HCl

Home from the hospital. He went in with a psychiatric emergency but left more like himself—delusions, hallucinations, and other psychotic target symptoms under control with 'Thorazine'. And 'Thorazine' maintenance can help keep him out of the hospital in the future.

From initial psychiatric emergency through maintenance therapy, 'Thorazine' offers effective antipsychotic therapy with 18 convenient dosage forms and strengths. This means you can precisely tailor dosage to the individual patient's needs throughout the entire course of therapy.

'Thorazine'. The most widely tested and highly flexible antipsychotic available today.

Helps return psychotic patients to reality

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose states, presence of large amounts of C.N.S. depressants, or bone marrow depression.

Warnings: The possibility of extrapyramidal reactions from 'Thorazine' may confuse the diagnosis of Reye's syndrome or other encephalopathy. Therefore, avoid use in children or adolescents with suspected Reye's syndrome.

Avoid using in patients hypersensitive (e.g., blood dyscrasia, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery) especially during the first few days' therapy. Avoid concomitant use with alcohol. May counteract antihypertensive effect of guanethidine and related compounds.

Use in pregnancy only when essential. There are reported instances of jaundice or prolonged extrapyramidal signs in newborn whose mothers had received chlorpromazine.

Precautions: Use cautiously in persons with cardiovascular, liver or chronic respiratory disease, or with acute respiratory infections. Due to cough reflex suppression, aspiration of vomitus is possible. May prolong or intensify the action of C.N.S. depressants, organophosphorus insecticides, heat, atropine and related drugs. (Reduce dosage of concomitant C.N.S. depressants.) Anticonvulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or obscure diagnosis of conditions such as intestinal obstruction, brain tumor, and Reye's syndrome (see Warnings). Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only). Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only). Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg. Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Special psychiatric problems demand specific references...

TRY THESE FROM MOSBY

A New Book! **MASSACHUSETTS GENERAL HOSPITAL HANDBOOK OF GENERAL HOSPITAL PSYCHIATRY.** Edited by Thomas P. Hackett, M.D. and Ned H. Cassem, M.D.; with 22 contributors. Here's a valuable new reference for the psychiatrist functioning as a member of the medical team. Emphasizing the management of general (non-psychiatric) hospital patients, it provides answers to common psychosocial problems of patients whose primary problem is physical rather than mental. Informative discussions examine major medical and surgical disorders which may be compounded by depression, hysteria, and other disruptive states. November, 1978. 612 pages, 13 illustrations. **Price, $14.95.**

A New Book! **THE CHILD AND DEATH.** Edited by Olle Jane Z. Sahler, M.D.; with 29 contributors. In a society geared toward denying death at any age, the death of a child is particularly traumatic. This insightful new book can assist you in helping parents, siblings, and health care workers cope with — and work through — a difficult problem. It uses a multidisciplinary approach to describe family structure and adaptation to loss, and explain children's reactions to the death of a parent or sibling. Ethical, religious, and educational questions associated with the family and dying are evaluated. November, 1978. 318 pages, 7 illustrations. **Price, $9.95.**

A New Book! **HEADACHE AND HEAD PAIN: Diagnosis and Treatment.** By Robert E. Ryan, Sr., M.S. (Otolaryngology), M.D., F.A.C.S. and Robert E. Ryan, Jr., M.D. Headache is one of your patients' most common complaints. Its origin could be anything from psychogenic to a brain tumor. Therefore, diagnosis is a real challenge. This book can help because it stresses the differential diagnosis and management of headache through pharmacotherapy and psychological reassurance. Definitive information on diagnosis and history taking make this a practical resource. October, 1978. 244 pages, 30 illustrations, 5 in 3-color. **Price, $39.50.**

2nd Edition. **THE LANGUAGE OF MENTAL HEALTH.** By William E. Fann, M.D. and Charles E. Goshen, M.D. This carefully updated edition includes the most modern terminology used in five areas of the mental health field: mental disorders, human behavior, treatment, administration and law, and related sciences. The authors have retained the appendices that were popular in the first edition — slang, abbreviations, colloquial English terms, and historical biographies. They have also added a valuable index of terms defined in the text. 1977. 175 pages. **Price, $9.50.**

BSP
Blackwell Scientific Publications

New from Blackwell! **THE ESSENTIALS OF CHILD PSYCHIATRY.** By Helen Connell, M.B., B.S., B.Sc., D.C.H., D.P.M., M.A.N.Z.C.P., M.R.C.Psych. Add this informative reference to your professional library. It discusses in detail normal psychological development and offers sound principles for the management of psychological problems of childhood and adolescence. Especially helpful chapters include: "Children's reaction to stress," "Childhood psychoses," "Personality and conduct disorder," and "Children's reaction to physical illness." 1978. 228 pages, 12 illustrations. **Price, $16.95.**

From Blackwell! **CLINICAL PSYCHIATRY.** By J. Willis. 1976. 482 pages. **Price, $24.75.**

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality, and authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2-6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

The February 1979 issue of

The American Journal of Psychiatry

will feature

- Short-Term Dynamic Psychotherapy
  By Judd Marmor

CHARLES C THOMAS • PUBLISHER

SOCIAL CONFLICT AND MENTAL HEALTH SERVICES *by* **Robert D. Borgman,** *Univ. of Southern Mississippi, Hattiesburg.* The author integrates social conflict theory with phenomenological, developmental, and problem-solving techniques to provide a singularly effective framework for understanding and intervening in the lives of troubled and troublesome individuals and families. Topics include mental patienthood, suicide and homicide, sexual oppression, school aversion, social conflicts of adolescence, menopausal distress, and problems of the elderly. *'78, 356 pp., cloth-$24.50, paper-$18.50*

THE DIAGNOSIS AND TREATMENT OF ALCOHOLISM (2nd Ed.) *by* **Gary G. Forrest,** *Psychotherapy Associates, Colorado Springs, Colorado.* The initial portion of this new edition discusses individual and social problems associated with alcoholism. Information is included on personality characteristics, developmental stages, sociological and physiological considerations, and diagnosis. The following section is devoted to current treatment strategies: psychotherapy, behavior therapy, residential treatment, and disulfiram maintenance. Clinical and research data on such topics as self-disclosure, hidden alcoholics, and the alcoholic power fantasy are presented in the final segment. *'78, 364 pp., 7 tables, cloth-$17.50, paper-$12.95*

ADULT ASSESSMENT: A Source Book of Tests and Measures of Human Behavior *by* **Richard S. Andrulis,** *The American College, Bryn Mawr, Pennsylvania. Contribution by* **John Bajtelsmit.** This comprehensive source book of adult behavior assessment describes instruments for measuring adult behavior and focuses on current and critical issues in testing. The volume begins with a clear presentation of practical, descriptive information on assessment devices and follows through with a delineation of the process by which one can identify and select the instrument most suitable for a given purpose. *'77, 340 pp., $14.50, spiral (paper)*

MUSIC AND THE BRAIN: Studies in the Neurology of Music *edited by* **Macdonald Critchley,** *National Hospital for Nervous Diseases, and* **R. A. Henson,** *The London Hospital, both of London, England. Foreword by* **Sir Michael Tippett.** *(22 Contributors)* All aspects of the neurology of music are covered in this definitive text. Such topics as hearing, genetics, movement, the nervous control of voice production, psychology of musical talent, musical memory, synesthesia, and brain anatomy and physiology as related to music are discussed in the initial sections. Later chapters contain contributions on musicogenic epilepsy, mental illness in composers, neurological illness in performing musicians, deafness, occupational palsies, and music therapy. *'77, 476 pp., 59 il., 6 tables, $34.00*

THE EVOLUTION AND CHEMISTRY OF AGGRESSION *by* **Delbert D. Thiessen,** *Univ. of Texas, Austin. Foreword by* **I. Newton Kugelmass.** This text explores the phylogenetic history of aggression; outlines several genetic correlates of aggression; shows how competition shapes the social and reproductive organization of populations; suggests that human aggression is partially determined by genetic factors and mediated through biochemical and morphological attributes; examines the hormonal control of aggression; reviews the significance of chemosignals; and discusses brain biochemistry and how pharmacological substances affect aggression. *'76, 232 pp., 38 il., 27 tables, $21.50*

PROGRESS IN BEHAVIOR THERAPY WITH DELINQUENTS *compiled and edited by* **Jerome S. Stumphauzer,** *Univ. of Southern California, Los Angeles. (43 Contributors)* This newly published volume gives a concise presentation of current issues and innovative therapeutic programs now utilized in treating juvenile offenders. Introductory discussions review history, cognitive issues, and a new project for developing cognitive self-control in young aggressive boys. Remaining chapters cover a wide range of treatment, training, and preventive programs in both institutional and community settings. A short introduction to each chapter details its importance, notes related work, and suggests further research. *'78, 440 pp., 37 il., 31 tables, cloth-$29.75, paper-$22.75*

NEXUS PSYCHOTHERAPY: Between Humanism and Behaviorism *by* **Kenneth Urial Gutsch,** *Univ. of Southern Mississippi, Hattiesburg, and* **Jacob Virgil Ritenour, II,** *Jackson, Michigan. Foreword by* **Howard S. Rosenblatt** *and* **Harold H. Dawley, Jr.** Concerned with the psychotherapeutically significant links between humanism and behaviorism, this book deals with emotions, behavior, values, and motivation. The authors explain that man is more than a passive creature whose existence is determined totally by stimulus and response. Man is also more than a collection of introspective experiences. They contend that elements of each of these views are valid, and that the key to understanding lies in a rational combination of both behavioristic and humanistic philosophies. *'78, 196 pp., 15 il., 16 tables, $16.25*

SENSORY ISOLATION AND PERSONALITY CHANGE *compiled and edited by* **Mark Kammerman,** *Labyrinth Corp., Beverly Hills, California. (13 Contributors)* Experts in experimental psychology and psychiatry have contributed their thoughts and research on the status of experimental sensory isolation and have assessed its potential as a tool for personality change. The effects of sensory deprivation in both bed confinement and water suspension isolation are detailed, as are the uses of sensory isolation as a method of exploring the unconscious mind. *'77, 324 pp., 2 il., 39 tables, $14.75*

GROUP COUNSELING AND GROUP PSYCHOTHERAPY WITH REHABILITATION CLIENTS *edited by* **Milton Seligman,** *Univ. of Pittsburgh, Pittsburgh, Pennsylvania. (18 Contributors)* Group work is discussed in relation to drug and alcohol abusers, the disadvantaged, stroke patients, the physically disabled, those with sensory impairments, the mentally retarded, the terminally ill, and public offenders. Topics include the peer self-help phenomenon, funding priorities, training programs, and processes that characterize the conduct of most groups. *'77, 352 pp., 1 il., 7 tables, cloth-$19.00, paper-$14.75*

HUMAN BEHAVIOR GENETICS *compiled and edited by* **Arnold R. Kaplan,** *Ohio Dept. of Mental Health and Mental Retardation Research Center, Cleveland. (21 Contributors)* Genetic aspects of individual differences in human behavior, personality, perception, intelligence, neuroticism, and psychological disorders are examined in this engrossing book. Associations between human behavioral variables and those in body build, biochemistry, and other objectively measurable biological variables are reviewed. A glossary of technical terms and an extensive author index are included for further reference. *'76, 496 pp. (6 3/4 x 9 3/4), 69 il., 86 tables, $78.00*

A11

Hallucinations... delusions... thought disorders... controlled

Navane (thiothixene) rapidly controls hallucinations as well as the agitation and hostility patterns they frequently generate.

Rapid control of psychotic symptoms on admission

Navane provides effective, rapid control of the major symptoms of psychosis including hallucinations, delusions, agitation, hostility, and thought disorders.[1-5] Navane promotes rapid progress, usually without the over-sedation or cardiovascular problems that can impede the therapeutic course.

Continued long-term improvement

Because Navane provides long-term outpatient control of psychotic symptoms, it can enable many patients to function effectively at home and on the job and to adjust rapidly to the community.[6]

Effectiveness rarely compromised by adverse reactions

Navane allows patients to remain alert and active, seldom causing over-sedation or drowsiness.[7] Hypotension and other cardiovascular reactions[5,6,8] are seldom reported and the occurrence of unpleasant anticholinergic side effects such as dry mouth or constipation is rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled through dosage adjustments or antiparkinson agents.

Rapid control
Long-term improvement

Navane®

(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml. Intramuscular 2 mg./ml.

A1

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane* (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
(thiothixene hydrochloride) Concentrate: 5 mg/ml,
Intramuscular: 2 mg/ml

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*—Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration—As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

SCHIZOPHRENIA

Towards a New Synthesis

Edited by J. K. WING

Progress in biochemistry has been made through investigations into the mode of action of certain drugs; genetics, through twins studies, has now produced, incontrovertible evidence for an inherited component in schizophrenia. Recent advances concern the way in which social and psychological factors percipitate onset and relapse and influence the course of schizophrenic disorders.

1978, 304 pp., $16.50 ISBN: 0-8089-1140-6

NEW—3RD EDITION

RORSCHACH'S TEST

VOLUME II: Gradients in Mental Disorder

(*previously entitled "A Variety of Personality Pictures"*)

By S. J. BECK, Ph.D.

The book discusses basic psychological theory on which the test rests. It affords fresh understanding into dynamics of personality, and new insights into meanings of test data growing out of changes in scorings since the earlier edition. Presented, as found in Rorschach's test, are continuum of mental states from the most handicapped up to heads of a society; the time factor—its effect on schizophrenic children; in an adult psychosis; before and after psychoanalysis, clarification of technical problems.

1978, 464 pp., $18.50 ISBN: 0-8089-1121-X

NEW YORK UNIVERSITY POST-GRADUATE MEDICAL SCHOOL ANNOUNCES AN INTERNATIONAL SYMPOSIUM

ERGOT ALKALOIDS IN NEUROLOGIC, NEUROPSYCHIATRIC AND ENDOCRINE DISORDERS

Thursday and Friday May 10 and 11, 1979

The hallmark of this broadly based symposium is the presentation of important investigative and clinical data at the cutting edge of applications of ergot alkaloids to the treatment of neuroendocrine disorders, Parkinson's disease and neuropsychiatric disturbances of aging. The material will be presented and discussed by internationally recognized authorities in their respective fields.

Opening review lectures set the stage for panel discussions, special workshops, case reviews and questions from the audience. Informal luncheons with the faculty provide registrants an opportunity to discuss subjects not presented in the general session.

The course is specifically designed for neurologists, endocrinologists, psychiatrists and physicians with a special interest in problems of female infertility, Parkinson's disease and gerontology and scientists whose research relates to neuropsychiatric and endocrine disorders.

Program Topics

- Pharmacology And Biochemistry Of Ergot Alkaloids
- Therapeutics Of Ergot In Neuroendocrine Disorders
- Parkinson's Disease And Other Neurological Disorders
- Ergot Alkaloids In Neuropsychiatric Disorders Associated With Aging

—WILLIAM SHAKESPEARE, *MACBETH*, ACT II, SC. 2

Insomnia
a shade of blue that often accompanies depression

And, in anxiety/depression, Adapin® (doxepin HCl) often helps restore disturbed sleep patterns, such as early morning awakening, with a single daily dose at bedtime. Adapin quickly relieves the patient's anxiety, gradually brightens his mood and outlook, with optimal antidepressant response usually evident within two to three weeks.

Brief Summary of Prescribing Information
ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.

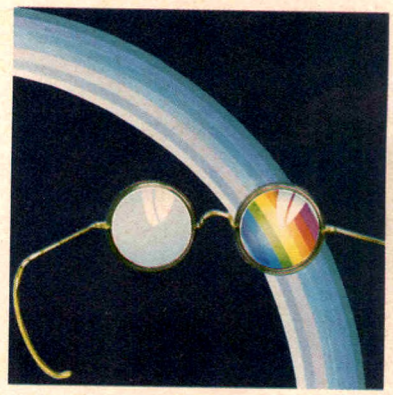
Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.



Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration—In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied—Each capsule contains doxepin, as the hydrochloride: 10 mg, 25 mg, 50 mg and 100 mg capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

INSOMNIA

that continues for up to two weeks outlasts most hypnotics.

ONLY **DALMANE**® (flurazepam HCl) C-IV

provides significant efficacy for chronic insomniacs from the first through 28 consecutive nights of investigation.

Objective investigations prove the continuing efficacy of Dalmane 30 mg *h.s.* during a 4-week medication period.[1-3] In contrast, a recently published sleep laboratory study reported the absence of a statistically significant hypnotic effect for chloral hydrate (1 Gm), ethchlorvynol (500 mg),* glutethimide (500 mg), methaqualone (250 and 400 mg) and secobarbital (100 mg) at the end of two weeks of administration.[4] Another study demonstrated that total wake time in insomniacs receiving pentobarbital (100 mg) returned to premedication baseline levels within 14 nights.[2]

Because insomnia is often transient, the prolonged administration of Dalmane is seldom necessary. If therapy must be extended, periodic blood counts and liver and kidney function tests should be performed.

*Another recently published study showed that ethchlorvynol (500 mg) did not result in a statistically significant reduction of sleep latency, minutes of wake time after sleep onset, number of nighttime awakenings and amount of wakefulness at medication nights 1-3 or at medication nights 12-14.[5]

Less risk of accidental or purposeful overdosage with Dalmane (flurazepam HCl)

"Flurazepam has a higher therapeutic index (lethal: hypnotic dose) than the other sedative-hypnotics; thus, there is less risk of accidental overdosage or potential use as a suicide agent."[6]

As with all medications of its type, Dalmane should be administered with caution to severely depressed patients or those with any evidence of latent depression. Protective measures should be taken for patients with suicidal tendencies.

Please see following page for a summary of product information.

ROCHE

FOR AN UNSURPASSED RECORD OF EFFECTIVENESS AND SAFETY

DALMANE®
(flurazepam HCl) C IV

30-MG AND 15-MG CAPSULES

One 30-mg capsule *h.s.*— usual adult dosage
(15 mg may suffice in some patients).
One 15-mg capsule *h.s.*— recommended dosage for elderly or debilitated patients.

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit dosage to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients.
Elderly or debilitated patients: 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Help cure cancer write now.

Thanks to your help, the tide is beginning to turn. The past few years have brought new discoveries in chemotherapy.
And new diagnostic techniques that combine the "eyes" of X-ray machines with the "brains" of computers. And successful new programs of combination therapies.
And there are promising reports coming in from research laboratories all over the world.
We now have everything we need to save about half the people who get cancer.
Please don't quit on us now.
We're halfway there.

American Cancer Society®
We want to cure cancer in your lifetime.

PLAN AHEAD!!!
Order your 1979 Appointment Book Now !!!

The "week-at-a-glance" Appointment Book, published by the American Psychiatric Association, has been developed over several years to satisfy the needs of as many members as possible. It contains a comprehensive list of addresses and annual meeting dates of all major organizations and agencies of interest to psychiatrists. Members who have not tried this book in the past are urged to do so. It is returnable within 30 days for a full refund if not acceptable. In addition, the name of the physician or hospital can be imprinted on the front cover for $1.00 a copy, providing that the order is received by July 15.

The Pocket Size Appointment Book is also available and can be ordered in combination with the Desk Appointment Book.

Copies will be available September 1978

MEDICAL HYPNOSIS AND SHORT-TERM PSYCHOTHERAPY

March 10-13, 1979 **Americana Hotel**
Bal Harbour, Florida

Robert T. London, M.D., and
James N. Sussex, M.D.
Program Co-Directors

sponsored by

The University of Miami
School of Medicine
Department of Psychiatry

A PRACTICAL DEMONSTRATION ON HOW AND WHEN TO EMPLOY HYPNOSIS AND SHORT-TERM PSYCHOTHERAPY IN OFFICE PRACTICE

Curriculum includes the use of the Hypnotic Induction Profile, psychotherapeutic strategies to be used by the physician with and without hypnosis, hypnosis in medical and surgical management and an over-view of short-term psychotherapy.

Tuition includes all course materials. Enrollment is limited and pre-registration mandatory.

Tuition: $195 Physicians in Practice
$125 Physicians in Training

Course hrs: 24, Category I

Letter from Chief of Service must accompany enrollment applications from physicians in training and non-physicians.

CONTACT: Division of Continuing Medical Education D23-3, University of Miami School of Medicine, P.O. Box 016960, Miami, FL 33101. Tel. (305) 547-6716.

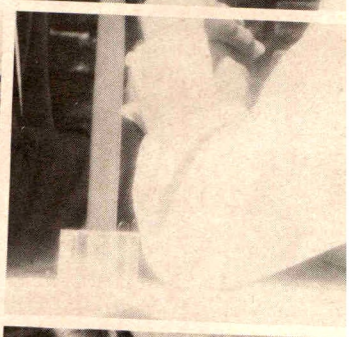
Merck Sharp & Dohme announces a new dosage strength

now dual-action® Triavil 4-50

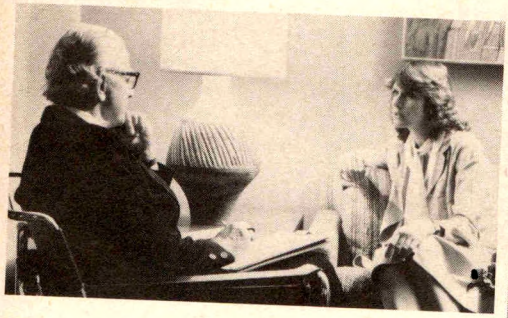
containing 4 mg perphenazine and 50 mg amitriptyline HCl

For even more dosage versatility in the treatment of marked agitation with depression

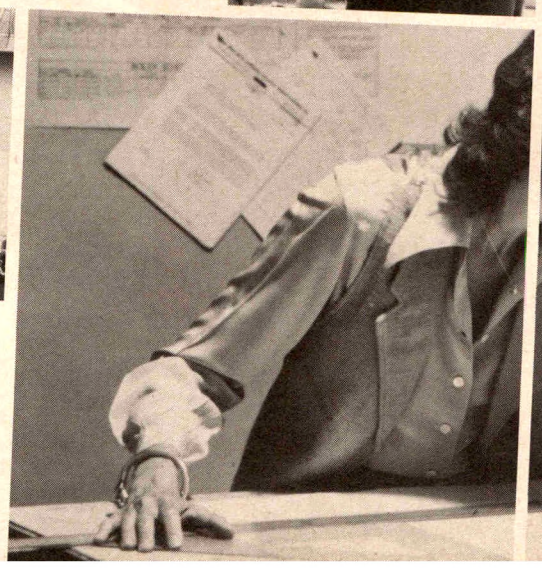
NEW dosage strength—to simplify therapy
five dosage strengths now available

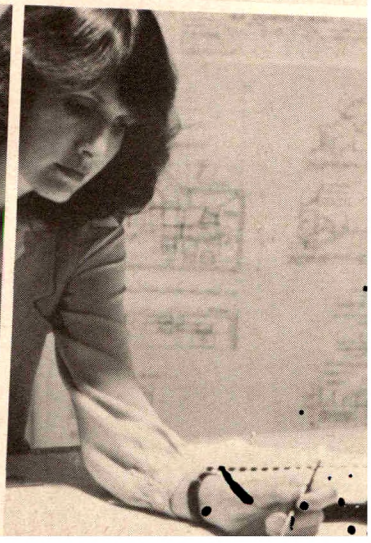


NEW option: b.i.d. regimen—to improve compliance
for initiating therapy
Rx TRIAVIL 4-50 b.i.d.



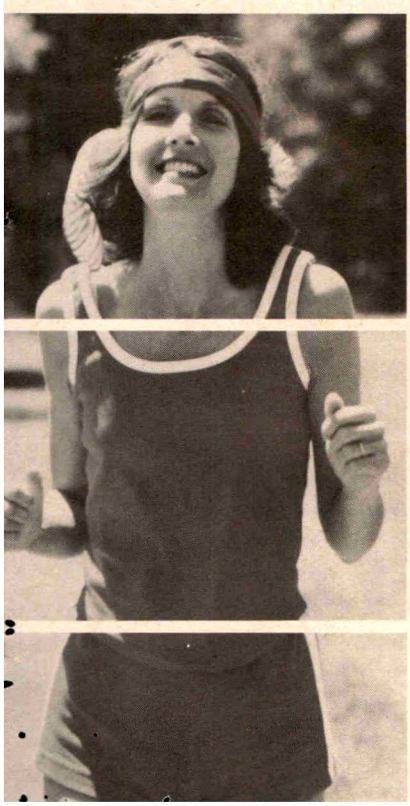
NEW unit-of-use package
bottles of 60 for 30 days of therapy, where appropriate





When TRIAVIL is part of the program, you may anticipate these therapeutic benefits for many patients:

Rapid antianxiety effect
The tranquilizer component can alleviate symptoms of anxiety and agitation within a few days. Hypnotic effects from the tranquillizer component appear to be minimal, particularly in patients permitted to remain active.



Highly effective antidepressant action
The antidepressant component can help relieve symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

...to aid the psychotherapeutic process
Patients often become more accessible and cooperative; symptomatic relief may enable the patient to function more effectively in his daily activities.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving. The drug may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to other drugs or mask other disorders. Since suicide is a possibility in any depressive illness, patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

MSD
MERCK SHARP & DOHME

Please see following page for a brief summary of prescribing information.

For a wide range of patients with marked agitation and depression

dual-action
Triavil®

containing perphenazine and amitriptyline HCl

now offers more dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

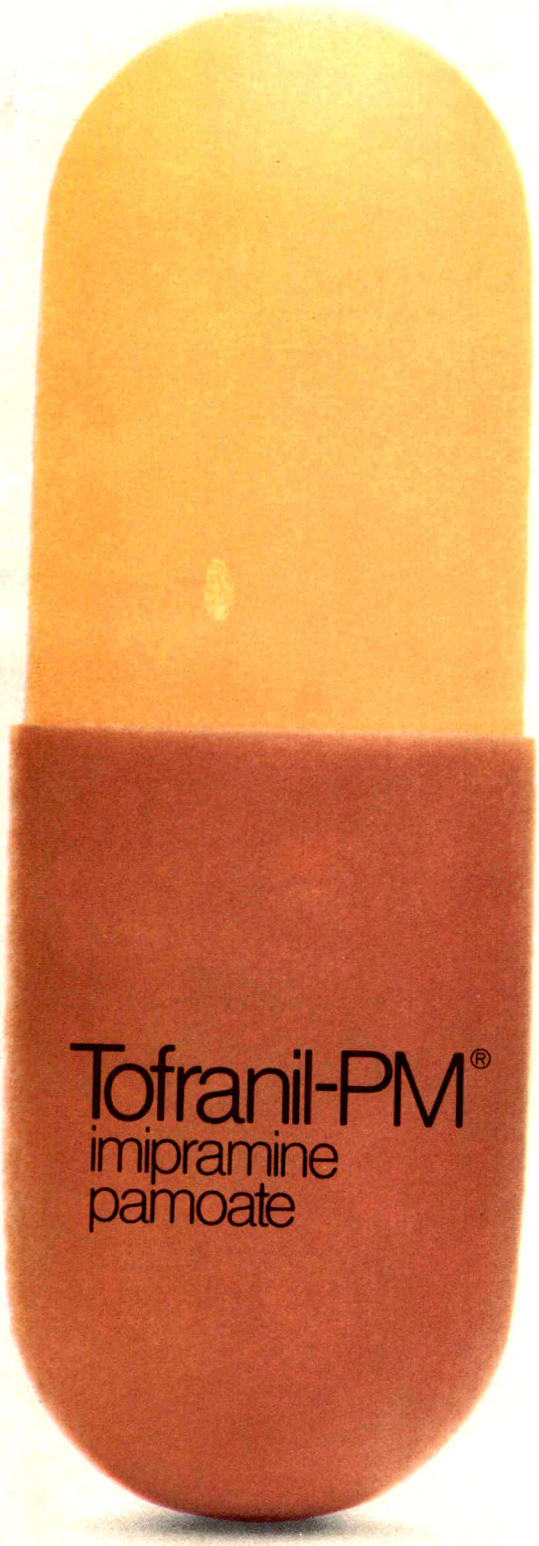
The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.



J8TR30 (DC6613215)

For more detailed information, consult your MSD Representative or see full Prescribing Information. Merck Sharp & Dohme, Division of Merck & Co., INC., West Point, Pa. 19486.

MSD
MERCK SHARP & DOHME

for many patients

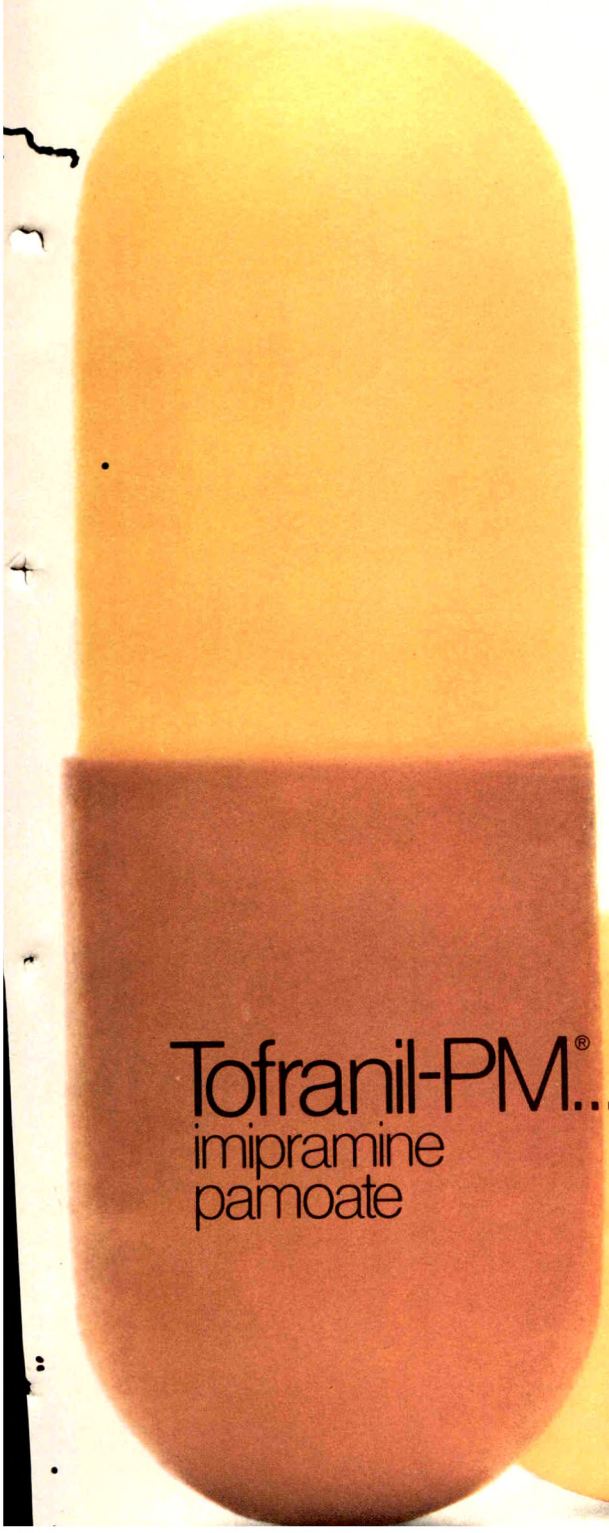
THE RIGHT ANTIDEPRESSANT

No tricyclic antidepressant works more effectively to brighten the mood, relieve sleep disturbances, and ameliorate mild anxiety.[1,2] And none appears to be better balanced[3] in terms of the biogenic amine theory of depression, which relates depression to functional deficiencies of the catecholamines.

For Tofranil-PM is almost equally effective in inhibiting the postsynaptic uptake of both serotonin and norepinephrine, the two neurotransmitters most often implicated in depression, while other tricyclic antidepressants tested are heavily skewed towards one or the other.*

*Nortriptyline, a chemical derivative of amitriptyline, also exhibits balanced action, but does not appear as effective in treating serotonin-mediated depression as imipramine.

Please see last page for a brief summary of the prescribing information.



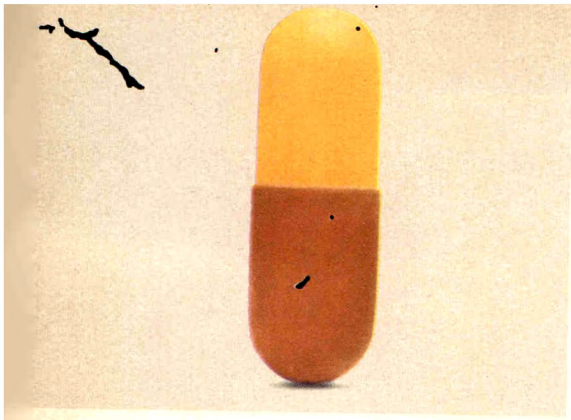
Geigy

for many patients
with mixed
anxiety-depression

THE RIGHT

Geigy

COMBINATION...



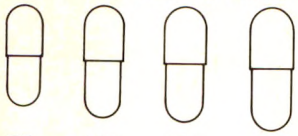
While Tofranil-PM alone exerts a sedative effect in depression, some patients with mixed anxiety-depression require the added control of a minor tranquilizer. For such patients, you can confidently prescribe diazepam (or virtually any other antianxiety agent) adjunctively with Tofranil-PM —unsurpassed among tricyclic antidepressants for its mood-brightening activity.[1, 2]

Tofranil-PM is effective when used alone or in combination regimens. Virtually any combination of psychotropics is possible—a flexibility difficult to achieve with fixed-combination antidepressant regimens.

The decision of which drugs to combine, and at what dosages, remains entirely in your hands . . . where it belongs.

Please see last page for a brief summary of the prescribing information.

Tofranil-PM®...plus **Valium** or any antianxiety agent
imipramine pamoate
(diazepam)



for many patients, the right antidepressant alone... or the basis of the right combination

Tofranil-PM® imipramine pamoate ...unsurpassed antidepressant action

For the majority of patients with neurotic depression, Tofranil-PM may be the only drug needed to produce a satisfactory brightening of mood.[1, 2] A recent report[4] notes that the two leading single-entity tricyclic antidepressants—imipramine pamoate (Tofranil-PM) and amitriptyline—provide equally effective antidepressant activity.

Better quality sleep—usually without morning "hangover"

Recent evaluation confirms that "...patients treated with imipramine pamoate tended ($P < .09$) to have a better quality of sleep than those treated with amitriptyline."[4]

75 mg 100 mg 125 mg 150 mg

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Many patients show good results on Tofranil-PM 75 mg h.s.; however, the most effective daily dose may be the 150-mg capsule.

Tofranil-PM®
imipramine pamoate

Each 100-mg. capsule contains imipramine pamoate equivalent to 100 mg. of imipramine hydrochloride.
Each 125-mg. capsule contains imipramine pamoate equivalent to 125 mg. of imipramine hydrochloride.
Each 150-mg. capsule contains imipramine pamoate equivalent to 150 mg. of imipramine hydrochloride.

Brief Summary of Prescribing Information

Indications For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.

The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

Warnings *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of imipramine, but a causal relationship has not been confirmed.

Extreme caution should be used when this drug is given to:

— patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
— patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
— hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
— patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
— patients receiving guanethidine or similar agents since Tofranil-PM, brand of imipramine pamoate, may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.

Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.

Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these episodes are relieved. Administration of a tranquilizer may be useful in controlling such episodes.

Prior to elective surgery, imipramine should be discontinued for as long as the clinical situation will allow.

An activation of the psychosis may occasionally be observed in schizophrenic patients and may require reduction of dosage and the addition of a phenothiazine.

In occasional susceptible patients or in those receiving anticholinergic drugs (including antiparkinsonism agents) in addition, the atropine-like effects may become more pronounced (e.g., paralytic ileus). Close supervision and careful adjustment of dosage is required when this drug is administered concomitantly with anticholinergic or sympathomimetic drugs.

Avoid the use of preparations, such as decongestants and local anesthetics, which contain any sympathomimetic amine (e.g., adrenalin, noradrenalin), since it has been reported that tricyclic antidepressants can potentiate the effects of catecholamines.

Patients should be warned that the concomitant use of alcoholic beverages may be associated with exaggerated effects.

Both elevation and lowering of blood sugar levels have been reported.

Concurrent administration of imipramine with electroshock therapy may increase the hazards; such treatment should be limited to those patients for whom it is essential, since there is limited clinical experience.

Adverse Reactions Note: Although the listing which follows includes a few adverse reactions which have not been reported with this specific drug, the pharmacological similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when imipramine is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke, falls.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurological: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic: Dry mouth, and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue); drug fever; cross-sensitivity with desipramine.

Hematologic: Bone marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathological neutrophil depression.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea; peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine: Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache and malaise.

How Supplied Tofranil-PM, brand of imipramine pamoate, is available as follows:

75-mg., coral-colored capsules equivalent to 75 mg. imipramine hydrochloride in bottles of 30, 100 and 1,000 capsules.

100-mg., dark yellow/coral-colored capsules equivalent to 100 mg. imipramine hydrochloride in bottles of 30, 100 and 1,000 capsules.

125-mg., light yellow/coral-colored capsules equivalent to 125 mg. imipramine hydrochloride in bottles 30, 100 and 1,000 capsules.

150-mg., coral-colored capsules equivalent to 150 mg. imipramine hydrochloride in bottles of 30, 100 and 1,000 capsules.

UNIQUE-NESS:

In People & at the Lutheran Hospital Psychiatric Care Unit

Providing complete psychiatric care in a general hospital setting with special emphasis on disorders of adolescence.

Lutheran Hospital of Milwaukee, Inc.

Basil Jackson, M.D., D.P.M., M.Th., D.Sc., F.A.C.P.
Chairman, Department of Psychiatry
2200 W. Kilbourn Ave., Milwaukee, WI. 53233

The Office of Continuing Medical Education
Albert Einstein College of Medicine

Announces Two Courses

Clinical Neurology For Psychiatrists:

Part 1 and Part 2

Under the Direction of

David M. Kaufman, M.D.

Department of Neurology
Montefiore Hospital and Medical Center

Part 1. Friday, Saturday, and Sunday; March 23, 24 and 25. This course, designed for psychiatrists preparing for the written part of the **American Board of Psychiatry and Neurology**, will consist of a series of lectures, videotaped demonstrations, and a practice written examination. **30 hours of Category 1 credit will be awarded.**

Part 2. Saturday and Sunday; October 6 and 7. the continuation, a course for candidates for the oral section of the Board, will review major neurological disorders by presenting audiovisual demonstrations and practice examinations. **20 hours of Category 1 credit will be awarded.**

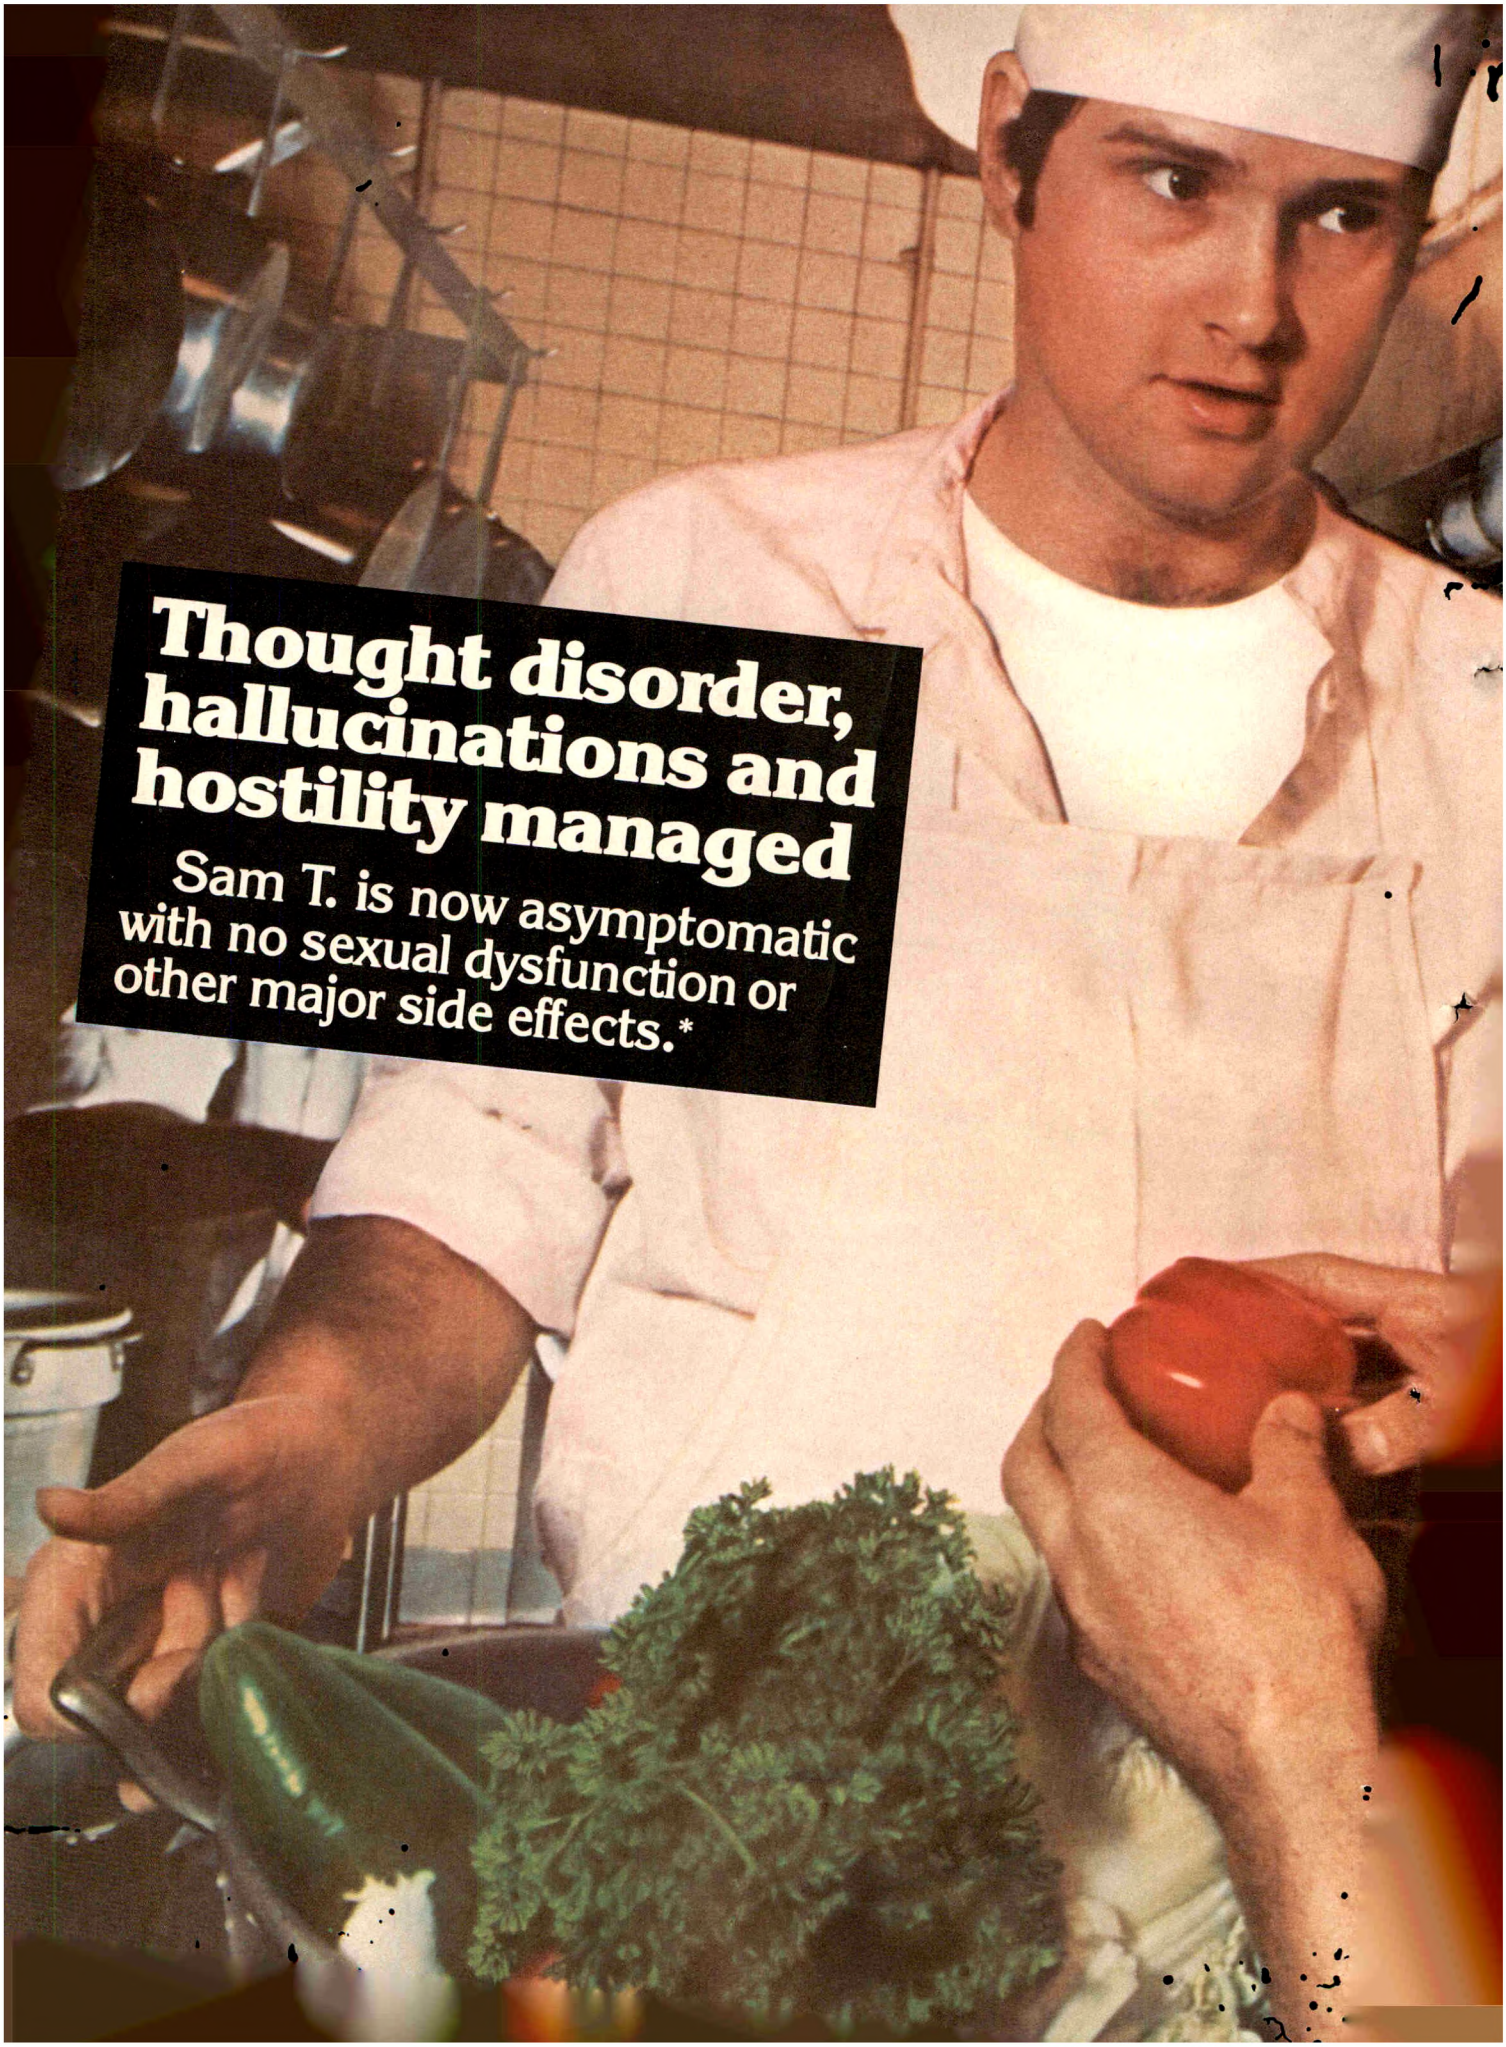
The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.



The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

An equal opportunity employer. All our programs are accredited by the appropriate Councils of the Joint Commission on Accreditation of Hospitals.

Thought disorder, hallucinations and hostility managed
Sam T. is now asymptomatic with no sexual dysfunction or other major side effects.*

LOXITANE® Loxapine Succinate

Permits rapid management of Sam's hostility and excited behavior

Thirty-six year old salad maker, claiming to be the "Wild Man of the West" was brought to the hospital by his kitchen supervisor. History revealed prior psychiatric hospitalizations and therapies including psychotropic drugs. Hypertension was noted as a complication of earlier treatment with anti-psychotic drugs. Diagnosis: chronic schizophrenia, acute exacerbation. He responded promptly to LOXITANE® C Loxapine HCl Concentrate 50 mg stat, followed by LOXITANE® Loxapine Succinate capsules 30 mg t.i.d.

Permits aggressive titration for rapid establishment of optimal management of Sam's thought disorder and hallucinations

During first week, LOXITANE dosage increased to 50 mg q.i.d. Significant improvement in thought disorder noted by third week. Auditory hallucinations and delusions much less frequent. Patient calmer and more cooperative.

Permits sustained symptom management with minimal risk of serious adverse effects, such as sexual dysfunction

Patient revealed that while on outpatient status, he failed to take his previously prescribed antipsychotic for a ten-month period after he met and married his girlfriend. He stated the drug "didn't let me be a man." No sexual dysfunction reported with LOXITANE.

Side effects are usually mild, transitory and easily managed

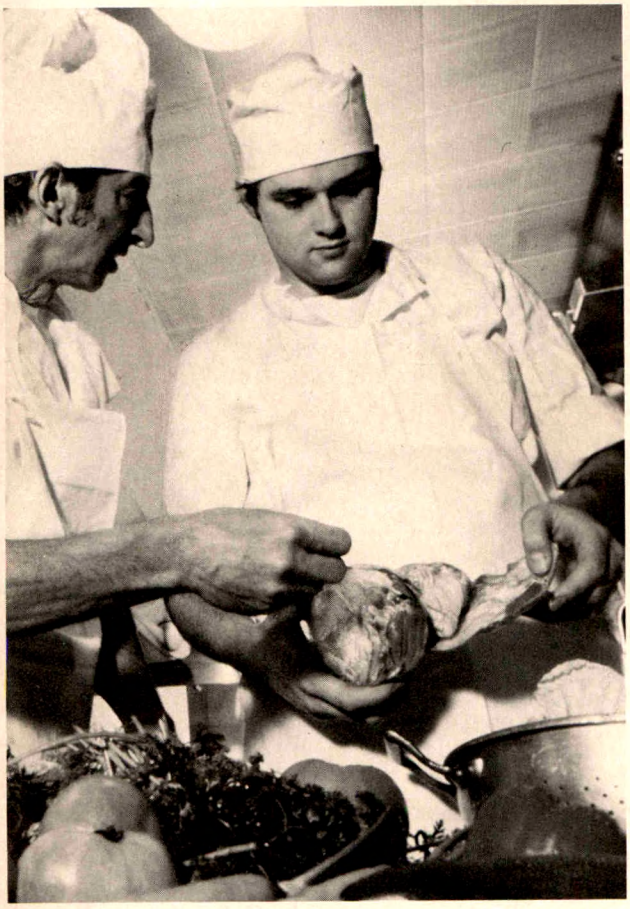
Patient felt anxious because his "heart was beating so fast," and he "could not sit still." Increased pulse rate and restlessness subsided following decrease of LOXITANE to 20 mg q.i.d.

Consistence in schizophrenic symptom management and tolerance promotes patient compliance

All admitting symptomatology under control by the fourth week. By the sixth week, he was anxious to return home. Stated "this medicine doesn't make me feel drowsy like the other did." Discharged by the eighth week. He returned to work fully managed on LOXITANE 20 mg t.i.d., and free from recurrence of previously reported side effects.

*Painful ejaculation and urine containing sperm have not been reported. Endocrine disturbances such as galactorrhea and menstrual irregularities have only been rarely reported. Other sexual side effects infrequently reported. Although not reported to date, possibility of hepatic, renal, ocular, or phototoxicity cannot be ruled out at this time. Transient liver enzyme changes not definitely related to LOXITANE have been reported. Not an actual patient, but a simulation to illustrate the action of LOXITANE as reported in clinical studies.

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.



Loxitane®

LOXAPINE SUCCINATE Lederle

Capsules:
5 mg, 10 mg,
25 mg, 50 mg

Maximum management... minimum risk

Maximum management... minimum risk

Loxitane®
LOXAPINE Lederle SUCCINATE

Recommended Daily Dosage

Initial Dosage	MILD	MODERATE	SEVERE
	10 mg b.i.d.	10 mg t.i.d or q.i.d.	25 mg b.i.d.
First 7 to 10 days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary
LOXITANE® Loxapine Succinate Capsules
LOXITANE® C Loxapine Hydrochloride Oral Concentrate
INDICATIONS: Manifestations of schizophrenia.
CONTRAINDICATIONS: Comatose or severely depressed states; hypersensitivity to the drug.
WARNINGS: Safe use during pregnancy or lactation has not been established; weigh potential benefits to possible hazards. Not recommended for use in children under 16. May impair mental and/or physical abilities especially during early therapy; warn ambulatory patients about activities requiring alertness and concomitant use of alcohol or other CNS depressants. Not recommended for management of behavioral complications in mentally retarded patients.
PRECAUTIONS: Use with extreme caution in patients with a history of convulsive disorders; use with caution in patients with cardiovascular disease or in those with glaucoma or a tendency to urinary retention particularly when on concomitant anticholinergic medication. Loxapine has an antiemetic effect in animals which might occur in man masking signs of overdosage of toxic drugs and obscuring intestinal obstruction or brain tumor. Since possible ocular toxicity cannot be excluded, observe carefully for pigmentary retinopathy and lenticular pigmentation.
ADVERSE REACTIONS: CNS effects, other than extrapyramidal, infrequent. Mild drowsiness may occur at beginning of therapy or upon dosage increase, usually subsides with continued therapy. Sedation, dizziness, faintness, staggering gait, muscle twitching, weakness and confusional states have been reported. Extrapyramidal reactions often occur early in treatment manifested by Parkinson-like symptoms (tremor, rigidity, excessive salivation, masked facies, akathisia) controllable by dosage reduction or antiparkinson drugs at usual dosages. Dystonic and dyskinetic reactions, while less frequently occurring, may be more severe, requiring dosage reduction or temporary withdrawal plus appropriate counteractive drugs. Persistent Tardive Dyskinesia may appear during prolonged therapy or following discontinuance, the risk greater in the elderly, especially females, on high dosage. Symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of the tongue, face, mouth and jaw sometimes accompanied by involuntary movement of extremities. Since there is no known effective treatment, discontinue all antipsychotic drugs if symptoms appear. Reinstitution of treatment, increased dosage, or switching to another agent may mask syndrome. The syndrome may not develop if medication is stopped when fine vermicular movements of the tongue first appear. Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness and syncope. ECG changes, not known to be related to loxapine use, have been reported. Skin: Dermatitis, edema of face, pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of unknown etiology seen in a few patients in hot summer months. Anticholinergic: Dry mouth, nasal congestion, constipation, blurred vision (more likely to occur with concomitant use of antiparkinson agents). Other: Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of unknown etiology.

Divide scored Endep tablets

+

Add flexibility to dosage titration

Long term treatment of depression with amitriptyline requires precise calculation of dosage to meet the individual needs of each patient. Because all six strengths of Endep are scored, you can easily increase or decrease dosage in half-tablet steps, without the bother and expense of a new prescription.

−

Subtract waste and cost

Scored Endep tablets permit you to adjust the regimen without wasting unused tablets or burdening the patient with the cost of a new prescription.

×

Multiply therapeutic options

The pharmacokinetic properties of Endep are such that its clinical effect is the same whether prescribed *t.i.d.* or as a single daily dose. Thus, once you have established the proper dosage, you can prescribe the entire dose *h.s.*, minimizing anticholinergic and sedative side effects, and helping to assure patient compliance with this simple regimen.

By prescribing the higher strength tablets *h.s.*—secure in the knowledge that the dosage can be adjusted without resorting to a new prescription—your patient will economize further on a per milligram basis.

Endep®

amitriptyline HCl/Roche

The only antidepressant scored for easy division

Endep
amitriptyline HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Contraindications: Known hypersensitivity. Do not use with monoamine oxidase (MAO) inhibitors or within at least 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Use not recommended during acute recovery phase after myocardial infarction.

Warnings: May block action of guanethidine or similar antihypertensives. Use with caution in patients with history of seizures, urinary retention, angle-closure glaucoma, increased intraocular pressure. Closely supervise cardiovascular patients, hyperthyroid patients and those receiving thyroid medications. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, including amitriptyline HCl, especially in high doses. Myocardial infarction and stroke reported with use of this class of drugs.) May impair alertness; warn against hazardous occupations or driving a motor vehicle during therapy. Weigh possible benefits against hazards during pregnancy, the nursing period and in women of childbearing potential. Not recommended in children under 12.

Precautions: May exaggerate symptoms in schizophrenic and paranoid patients, or shift manic-depressives to manic stage; reduce dose or administer major tranquilizer concomitantly. Close supervision and careful dose adjustments required when given with anticholinergic or sympathomimetic agents. Exercise care in patients receiving large doses of ethchlorvynol; transient delirium reported with concomitant administration. May enhance effects of alcohol, barbiturates and other CNS depressants. Because of the possibility of suicide in depressed patients, do not permit easy access to large drug quantities in these patients. Because it may increase hazards of electroshock therapy, limit concomitant use to essential treatment. If possible, discontinue drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: This list includes a few adverse reactions not reported with this specific drug but requiring consideration because of similarities of tricyclic antidepressants. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue. *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, jaundice, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache and malaise. These are not indicative of addiction.

Supplied: *Scored Tablets:* 10, 25, 50, 75, 100, 150 mg.

FLORHENAZ
PROLIXI

The Prolixin® (Fluphenazine) system of schizophrenia management—

spanning virtually every clinical situation

There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).

For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries.

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—1 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine decanoate per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Physicians should be alert to the possibility that severe adverse reactions may occur which require immediate medical attention. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician experienced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal functions and blood picture should be done. Renal function of patients on long-term therapy should be monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneumonias" are possible.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been reported following use of fluphenazine decanoate. One can expect a higher incidence of such reactions with fluphenazine decanoate than with less potent piperazine derivatives or straight-chain phenothiazines. The incidence and severity will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an antiparkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

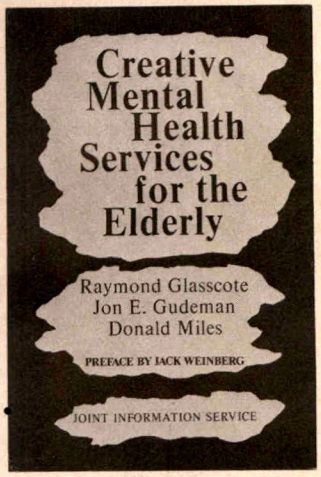
Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines. Local tissue reactions occur only rarely with injections of fluphenazine decanoate.

For full prescribing information, consult package insert.



HOW SUPPLIED: 1 ml Unimatic® single-dose preassembled syringes and cartridge-needle units and 5 ml vials.

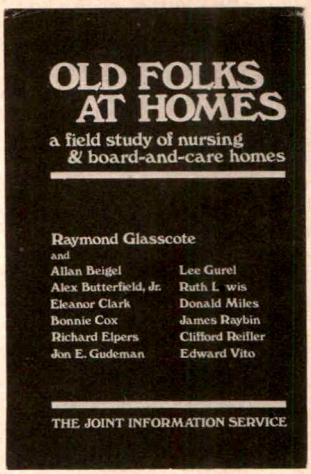
SQUIBB® "The Priceless Ingredient of every product is the honor and integrity of its maker."™

The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

Focus on the Elderly



This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."

190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting daily dose of 75 mg is recommended. Dosage may subsequently be increased or decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increase to 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as low as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a-day dosage schedule. If the once-a-day schedule is employed the maximum recommended dose is 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effect may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.
2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias and tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus), hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.
2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions to prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed. The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patients and assisted ventilation used if necessary. EKG monitoring may be required for several days, since relapse after apparent recovery has been reported. Arrhythmias should be treated with the appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intravenous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine is rapidly metabolized, the dosage should be repeated as required. Convulsions may respond to standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depression. Dialysis and forced diuresis generally are not of value in the management of overdosage due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 mg, and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg and 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 mg doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Oral Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrated at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 mg doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted with approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune or pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number of carbonated beverages. For those patients requiring antidepressant therapy who are on methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixed together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not with grape juice. Preparation and storage of bulk dilutions is not recommended.

THE AMERICAN JOURNAL OF PSYCHIATRY

Psychotherapy of the Medically Ill

BY TOKSOZ B. KARASU, M.D.

The author assesses the current status of psychotherapy with medically ill patients. He reviews the special problems of psychological treatment for this population; the respective rationales for the utilization of various psychotherapeutic approaches including psychoanalysis, dynamic psychotherapy, and family and group therapy; and the results of case reports and research studies. The author identifies specific areas of future investigation and research, elucidates some specific implications for clinical practice, and recommends more critical exploration of the role of psychotherapy in the treatment of the medically ill.

EXTENSIVE STUDIES of psychodynamic and psychological responses to life stress formulations continue to contribute to an increasing theoretical literature with important implications for psychological intervention; yet comparable strides have not been made in the efficacy of psychotherapy as a treatment modality for medical illness. It is generally believed by medical and psychiatric clinicians that psychosomatic patients are especially poor candidates for psychotherapeutic interventions, especially psychoanalysis (1–3). Wolff (1) considered three-quarters of his psychosomatic patients unsuitable for intensive, interpretive psychotherapy; Sifneos (2) observed that such patients actually get worse from the psychodynamic process. Sperling (3) has contended that whether one uses supportive therapy or psychoanalysis in the treatment of psychosomatic disorders, either approach is uneconomic: supportive therapy because the patient's dependency is never resolved and psychoanalysis because of the specialized skill required and the scarcity of qualified analysts who are properly prepared to treat such cases. These researchers and others have therefore suggested modifications of classical psychoanalytic techniques that may be applied when more orthodox methods have met with excessive resistance or failure (1–7).

Studies of the effects of psychotherapy for the medically ill have been relatively minimal and inconsistently controlled, and when globally evaluated for therapeutic results (physical and/or psychological), they have been equivocal in overall outcome (8–10). However, in one historical review of the effects of psychotherapy (11), the highly variable and null results were seen as embedded in the "outcome problem" of psychotherapeutic research design, that is, the typical misleading tendency to include assessments of psychological treatment at termination only. In reexamination of controlled follow-up studies of six months or more across a full spectrum of psychotherapeutic modalities (psychoanalysis, individual dynamic psychotherapy, and behavioral and group approaches) used with three psychosomatic conditions (ulcerative colitis, peptic ulcer, and asthma), *all* gave positive results. Strong evidence indicated that whether a psychodynamic approach per se is necessary and specific, it can be effective. Moreover, the almost bizarre conclusion was reached that dynamic therapies were validated as effective for psychosomatic conditions—and for no other diagnoses whatsoever, including the psychoneuroses. This review is intended to bring up to date the various findings that have been reported in this area and to critically assess the current state of the art of psychotherapeutic intervention for the medically ill.

Received Nov. 7, 1977; revised March 2, 1978; accepted June 19, 1978.

Dr. Karasu is Associate Professor of Psychiatry and Vice-Chairman, Department of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. He is also Director, Department of Psychiatry, Bronx Municipal Hospital Center, Pelham Parkway South and Eastchester Road, Bronx, N.Y. 10461.

THE SPECIFIC NATURE OF THE PROBLEM

Obstacles to psychiatric treatment include the complex nature of psychosomatic forms of illness that re-

UNIVERSITY OF MINNESOTA LIBRARY

0002-953X/79/01/0001/11/$00.80 © 1979 American Psychiatric Association

side on an intricate continuum of psyche. They include somatic influences and manifestations (12); the presumed personality characteristics, attitudes, and defense mechanisms of the patients that have direct implications for motivation for psychotherapy and conduct during treatment, e.g., profound resistance, denial of psychic conflicts (1–4, 6, 13–19); and, all too often, countertransference reactions of internists and psychiatrists themselves (1, 19, 20)—all of which converge on the treatment situation to make the practice of psychotherapy for psychosomatic illnesses a formidable, if not impossible, undertaking.

Major issues for psychological intervention include whether the patient with a psychosomatic disorder can sustain sufficient motivation for undertaking and maintaining treatment, that is, establishing a productive doctor-patient relationship, and, once in treatment, whether he or she can comprehend and withstand attending to the psychological side of the illness. In these regards it has been noted that persons with psychosomatic disorders characteristically set up the most rigid and archaic defense mechanisms of denial and reaction formation against the experience of affect (3) and are unable to experience and express negative feelings, particularly aggression (6). The irony of these mechanisms for psychological intervention per se is represented in the observation that the psychosomatic patient needs to use and attend to his or her physical symptoms for the very purpose of warding off psychological insights (16); indeed, a psychosomatic illness is said to develop when a patient is unable to acknowledge and tolerate an emotional conflict and its accompanying instinctual impulses (1). Moreover, while psychosomatic events typically declare themselves in connection with situations of stress arising from within the individual or his or her immediate environment, frequently the psychosomatic sufferer is not aware of such connections or of being under any particular stress (18).

In accordance with these observations, a psychosomatic character pattern has been elucidated. It encompasses the following: unusual object relationships, especially denoted by a lack of libidinal affect; an impoverished use of language in which operational thinking (i.e., extremely detached and pragmatic) predominates; an inability to use regression or dream-type functioning; and a marked lack of neurotic symptoms and neurotic character adaptations, with facial movements, bodily gestures, sensory-motor expressions, and physical pain manifested when one might otherwise expect neurotic behaviors (14).

Directly related to motivation for treatment have been the observations that many psychosomatic patients consider psychological conflict as a sign of weak character, emotional problems as synonymous with malingering; that revealing one's dependency is typically considered shameful (5); and that the ulcer patient would finally agree to psychiatric treatment not because of a recognition of his or her own needs, but only when he or she was convinced that he or she was doing it for someone else, i.e., helping the doctor (21). Others have confirmed that the patients with the most severe and long-standing illnesses were those most unable to tolerate having their denial shaken and were most prone to terminate treatment prematurely (7, 16). That is, when these patients begin to see that the physical symptoms of others are related to life difficulties and when they are forced to realize that their *own* physical problem may have the same basis, they do not return to therapy.

The manifestations of these features during the psychotherapy process have included the observations that preliminary interviews with psychosomatic patients were pervaded by a type of inertia that threatened to bring discussion to an end; that the investigator had to make vigorous efforts to stimulate associative material concerning the patients' relationships, life experiences, and illness; that significant or painful events were overlooked unless directly solicited and were recounted with minimal emotional expression (14); and that even when the patients' symptoms inflict physical pain, they fail to receive much attention during the therapeutic encounter (18). This was characterized both by a physiological hardiness or attitude of blithe disregard for one's own physical welfare as though the body were a decathected object and a psychological hardiness or refusal to give in to psychic pain, anguish, or depression.

Psychosomatic patients generate an impression of superhuman emotional control, behind which appears to reside the necessity to refuse to reveal one's needs, dependency, disappointment, anger, despair, or any incapacity or failure. Weisman (22) attributed this to the ego ideal of these patients, which is "inaccessibly high"; and Castelnuovo-Tedesco (23) noted, especially in ulcerative colitis patients, a fundamental "compliance-versus-rebellion" conflict that is resistive to the treatment situation. In the analytic situation aloofness, detachment, testiness, irritability, and contentious demandingness regularly came to the fore in situations that signify being humiliated, coerced, or otherwise used or violated. More globally, it is said that most psychosomatic patients in psychological treatment possess "a negative attitudinal set" (6).

Mushatt (13) found that ulcerative colitis patients were unable to free associate and could not tolerate therapist silences. Sifneos (2) observed that psychosomatic patients had little to talk about and were unable to explain to the therapist why they found the transference situation so discomforting. Stevens (24) found that the transference and interpretation in psychotherapy, especially in psychoanalysis, mobilized enormous anxiety in these patients, which they found intolerable. Struck by psychosomatic patients' marked unamenability to classical dynamic psychotherapy, Sifneos significantly validated the prevalence among these patients of a group of characteristics that would resist and even be antithetical to the analytic process. They include poverty of fantasy life, constriction of emotional functioning, inability to find appropriate

words to verbalize feelings, and absence of an ability and motivation for self-examination. Sifneos found that 25 psychosomatic patients had twice as many of these so-called "alexithymic" characteristics as did 25 control subjects (17).

The fragile egos of these patients, as well as the particular nature of their defensive structure, has another significant implication for psychological treatment. Just as the removal of the latent psychotic patient's neurotic defenses can produce an acute psychotic episode, the analysis of the psychosomatic patient's strong denial and reaction formations can bring about not an amelioration, but an aggravation, of the patient's somatic condition (3). It is also reportedly feared that analytical psychotherapy of patients with psychosomatic illness is likely to precipitate a psychotic breakdown; however, according to Wolff (1), this has never occurred in his experience.

Aside from the psychosomatic risks and resistances of the patients are the reactions and counterreactions of internists and psychiatrists themselves to the psychological treatment of psychosomatic disorders. Wolff (1) has pointed out the difficulty of overcoming medical practitioners' reluctance to refer the patient to a psychotherapist, especially if the medical regimen has met with some success, and the tendency to regard psychotherapy as the last line of medicine for any disorder that appears to be a physical illness. Even when the medical doctor's resistance has been overcome, psychotherapists themselves may be disenchanted with the prospect of treating persons with apparently organic, often life-threatening, illnesses. Craddock (20) has referred to the limited psychiatric experience with and knowledge of these diseases, which discourage attempts at psychological treatment. Fain and Marty (19) have noted the risk to the analyst, who may feel that such patients constitute a chronic narcissistic blow to his or her interpretive powers and who may react with a countertransferential lack of interest. Moreover, the fear that too early or too direct a confrontation may result in the very early termination of treatment, intense negative transference, the possible precipitation of a psychotic breakdown, or, more likely, an acute exacerbation of the very illness that is being treated, even the risk of death, becomes a matter of particular delicacy and concern for the prospective psychotherapist of the medically ill patient.

PSYCHOANALYSIS AND INDIVIDUAL PSYCHOTHERAPY

Rationale of Treatment

Theories about the etiology of psychosomatic disorders and their manifestations in the patient naturally have implications for what one views as the treatment of choice. Long-term psychotherapy, especially psychoanalysis, as an essential aspect of treatment largely develops out of models of psychosomatic illness that have specific psychogenic factors (e.g., psychological defenses, predispositions, precipitating psychosocial situations, early life experiences, specific affects), and especially psychological conflict (e.g., dependency), as their pivot point in the etiology of disease-specific physiological patterns (3, 25–27). In addition, the possible role of infantile psychophysiological patterns of function has highlighted the need to address crucial developmental phases in psychotherapy (28, 29). The roles of object loss and reactive response to illness (especially the affects of helplessness and hopelessness), separation, symbolic functions, and conversion mechanisms in the impact of illness on body image have reflected the need to deal with reactive issues, depression, and object relations in treatment (30–32).

Clinical Cases and Research Studies

Much of the psychoanalytic groundwork for psychosomatic disorders exists in the form of detailed clinical case studies (3, 23, 33–35). Sperling (3) reported the successful treatment of several children with severe psychosomatic disorders. In the course of child play analysis for a 4-year-old with ulcerative colitis, the child's complete submission to his mother was radically altered. When the first manifest displays of his aggression appeared, they were accompanied by an immediate and striking improvement not only in the illness but in the child's total behavior (3). A 10-year-old asthmatic boy remained asthma-free for the 2 years during his analysis plus 9 years subsequent to it (33). There were comparable results with an 8-year-old boy with asthma after just 7 months of treatment (34). However, along with these highly encouraging outcomes were certain dangers: the development of a very strong transference neurosis, which culminated in a severe asthmatic attack; soiling and nightmares correspondent with improvement; and more frequent asthmatic attacks in a family member, who became more difficult in general. These authors emphasized the importance of early treatment for maximal therapeutic success.

The treatment of adults has been less consistent in outcome. In striking concordance with efforts to make a colitis/gout patient aware of the destructive implications of his marked dependency, his attacks became increasingly frequent, resulting in at least 25 major exacerbations during the 3 years of psychiatric treatment. The patient's colitis had occurred primarily in response to coercion by a significant person, whereas the gout attacks were precipitated by real or threatened separations or when issues of independence were uppermost (35). Stein and associates (36), who studied the changes in hydrochloric acid secretion in a patient with a gastric fistula during 2½ years of intensive psychotherapy, found that 8 months after the psychotherapy was begun, the high normal level of the gastric hydrochloric acid dropped abruptly and remained at a low level for 12 months. This striking change occurred when the patient became aware of and began to express material related to her oral-aggressive drives.

In conclusion, individual case reports of success-

ful psychoanalysis for patients with psychosomatic disorders, especially children, have been clinically impressive but subjectively anecdotal and impressionistic. In addition it is ironic that the focus on the relationship between course of treatment and exacerbation of illness makes it appear that exacerbations are often triggered by the very process of "cure." Finally, however dynamically relevant and therapeutically positive such studies are, they leave unanswered the question of evidence by omission. As Freeman and associates (37) noted, "One must wonder how many failures go unreported" (p. 599). However tantalizing the above findings, the need for data from larger samples is becoming increasingly apparent.

A larger, more systematic study of dynamic/therapeutic relationships was conducted by Weisman (22), who found that six men treated with psychoanalysis had fewer recurrences of symptoms than did untreated individuals. No single specific variable could account for the frequency and duration of exacerbations, or length of symptom-free intervals. However, in one case the exacerbation of ulcer symptoms occurred with the threat of depletion of the therapist's "love"; the controlled release of the patient's restrained anger was considered an important aspect of treatment.

Weinstock (38) reported the results of the first national questionnaire survey of psychoanalytic treatment by experienced analysts in 25 cases of severe ulcerative colitis, in which previously hospitalized patients were treated for long periods (1½ to 5 years). Approximately 80% of them were symptom-free for 3 to 18 years, with a median "cure" period of 9 years. The 20% with poorer results were primarily those with severe, unremitting symptoms for an average period of 9 years before treatment. The two modalities used (psychoanalysis and psychoanalytically oriented psychotherapy) were not significantly different in overall effect, and the analysts concluded that psychiatric treatment per se had been the decisive factor in maintaining the patients' symptom-free status.

Perhaps the most extensive and revealing series of matched controlled studies represent three decades of observation and psychotherapy of ulcerative colitis patients (39–43). In the initial study, 5 completely analyzed patients showed greater psychological improvement than those unanalyzed, suggesting that even a few well-timed and insightful sessions can serve to release impounded anger and lead to better life adjustment (39). In a much more intensive study, 57 patients who had received psychotherapy in addition to the usual medical regimen had more favorable somatic and psychological responses than did a matched control group. Of the total group of patients, 75% improved psychologically and 66% somatically. In most cases there was a simultaneous increase or decrease in both psychological and somatic responses, a concomitance rather than alternation of symptoms, i.e., overt signs of emotional disorder appeared most frequently during exacerbations rather than remissions of the somatic symptoms (16). The length of treatment also had interesting effects on symptoms. When proctoscopic and symptomatic ratings were recorded over an 8-year period, a definite pattern emerged. In the first year of psychotherapy the treated patients rated consistently lower than the control group; in the second and third years there was sustained improvement; and in the fourth to eighth years there was marked improvement (the control group remained essentially the same throughout the 8 years) (40).

Later studies compared 30 colitis patients with controls on pretreatment factors (41) and on a variety of "psychotherapeutic situation" factors (42). The following four pretreatment factors had clear implications for poor psychotherapeutic prognosis: severe psychopathology, significant symbiotic dependency, little ego strength, and a significant drive for secondary gain from the illness. Within the psychotherapeutic situation per se, the most lasting somatic improvement derived from a combination of high patient hope and high therapist interest, empathy, and optimism. In terms of specific technique, interpretation proved most valuable only with active-individuated patients in whom symbiosis was a minor issue; passive-symbiotic types did most poorly with interpretation. Psychoanalysis was precluded during attacks of colitis in any patient. Briefer and less intensive uncovering techniques (44–46) were able to bring about significant somatic improvement in most patients, but the longer therapies were almost twice as effective in promoting and maintaining remissions of the disease (42).

In conclusion, although the difficulties (3, 33, 35) as well as the successes (3, 22, 33, 34, 36, 38–40) of analytic approaches and insight-oriented psychodynamic therapies have been amply reported, ultimately only carefully controlled research studies that take into account such significant variables as length of treatment (40), pretreatment patient factors (41), and therapist qualities and specific techniques (42) will determine their feasibility and effectiveness and the degree to which therapeutic alternatives (e.g., supportive approaches) are needed.

FAMILY THERAPY

Rationale of Treatment

Insofar as the fundamental dynamics of the mother-child relationship have been regarded as crucial to the psychosomatic pattern of response, it is felt that severe psychosomatic disorders may be reversible if it is possible to directly change the relationship (i.e., "mutual symbiosis") existing between mother and child (3, 33). In young children, especially, this goal can be particularly well accomplished in the concomitant treatment of mother and child, "where a modification of the unconscious need of the mother [can] manifest itself in a change in the somatic response of the child" (3, p. 281). More generally, the basic thesis behind most family treatment is that the child with a psycho-

somatic illness is the "symptom bearer" of the family and that the family system must be changed in order to enable the child to alter his or her special role in it (47–53). It is also believed that traditional, one-to-one, dynamically oriented approaches may fail with the chronic patient because they intensify his role as a sick member of the family while neglecting the roles of parents and siblings in perpetuating the illness. In brief, the symptoms are said to play an important role in the defensive structure of the family; they are hypothesized to be the consequence of a conflict-detouring process in which the parents' total concentration on, and infantilization of the child enables them to detour and avoid dealing with their own marital conflicts. Thus the psychosomatic disorder is seen as situated in the feedback processes of child and family, in which the family's feedback to the child's symptoms becomes an autonomous process that maintains the symptom.

Certain types of family organization or characteristics are said to be crucial to the development and maintenance of psychosomatic symptoms, which can be best addressed in family therapy. These characteristics include "enmeshment" (high degree of involvement with other members of the family), "overprotectiveness" (high degree of concern with each other's welfare), and "rigidity" (detouring conflict onto the child such that when the family's low threshhold of conflict is approached, the child becomes ill). The goals of family treatment are to identify and change family patterns that perpetuate the psychosomatic symptoms (47–54). In the conjoint treatment of patients and spouses, the rationales for family treatment include providing a more direct outlet for repressed rage (55) and helping to break the denial of the psychosomatic patient with the presence of another family member (4).

Research Studies

In her pioneering studies Sperling (3, 33) conducted psychoanalytic treatment of asthmatic children with their mothers either concomitantly or intermittently, and of the mother only when the child was the psychosomatic sufferer. In both types of treatment there was a remarkable improvement in the asthma of the child. This was attributed to the mother's having gained increasing insight into the ways in which she signaled her needs for the child to be sick and her increased ability to control them. In a controlled intensive study of 10 families of eczematous and asthmatic children, half of whom had attended a therapeutic nursery school, the eczematous symptoms markedly diminished (54). During the psychotherapy of the family the dynamics of eczematous exacerbations were revealed and changed; the hitherto covert conflict of the parents came to the fore; they began to verbalize quite openly their deep disappointment, frustration, and anger with each other; and the child began to be less infantilized and more assertive. However, it should be noted that asthmatic attacks appeared at this time. (The authors attributed the attacks to the disruption of the previous intrafamilial equilibrium.)

In an elaborate series of studies Liebman, Minuchin, Rosman, and associates (48–53) reported the use of structural family therapy in the treatment of intractable asthma, infantile diabetes, and anorexia nervosa. In the study of asthma (51) 7 patients were treated with weekly family therapy conducted in three phases with successive goals: alleviation of symptoms (through deep-breathing exercises with the father), identification and modification of family patterns that exacerbated and perpetuated severe symptoms, and the lasting disengagement of the patient from the family. Family therapy was considered successful in all cases. Six subjects did not experience acute attacks of asthma requiring hospitalization; all 7 were no longer dependent on chronic steroid treatment; they had more normal lifestyles in school and with their peers; they engaged in more physical activity; and there was a positive change in the interpersonal relationship of siblings and parents.

In the treatment of anorexia nervosa the authors developed a "family lunch session" as the focal point around which the family therapy was pivoted (50, 52). The lunch sessions had the major purpose of enabling the patient to eat in the presence of her parents without a power struggle, and the parents were given specific tasks that served to separate the patient from their conflicts. A research study of the effectiveness of this program showed a significant weight gain in all 8 of the anorectic children studied (52). Aponte and Hoffman (53) found that once the parents of an anorectic girl established a better relationship with each other, they could effect weight gain in their child for the first time. The girl gained 14.5 kg in 5 weeks, and 6 months later continued to be in good physical shape, had a boyfriend, and was leading a more independent life. Barcai (47), in two case reports, noted that each patient showed a continuous weekly weight gain of .9–1.4 kg from the time of the first therapeutic contact until normal weight was attained within 3 to 4 months. One, in fact, responded with disappearance of the symptom after a 2-hour family session. These results are in accord with earlier findings by Minuchin and Barcai (49).

Other studies of family treatment have involved the conjoint family therapy of husband and wife in the case of patients who somatize, especially those with chronic migraine headaches (4, 55). As a result of the conjoint family treatment of migraines, symptom relief was successfully obtained (although the patient's basic fear of aggressiveness remained unresolved) (55). In addition, although the conjoint family method did result in the prompt alleviation of symptoms, the therapist did not attribute the outcome to the use of this modality per se. Rather, he concluded, "this result appeared similar to that obtained by a new drug or new therapist and was probably attributable to providing a new sense of hope and security" (55, p. 63).

With regard to motivation, Raft and associates (4)

studied 20 patients for whom symptoms could be directly related to psychological conflict, but who upon individual interview refused to accept the relationship. Seventeen of the 20 patients, when interviewed individually, did not believe that psychiatric intervention was needed. As a result of a family interview, however, 80% of them accepted psychiatric recommendations and referral.

The above studies may be said to suffer the same pitfalls of other psychotherapy outcome studies (11). However, the application and utilization of family therapy techniques for psychosomatic illnesses have been lent substantial support by the study data and outcomes. The advantages of the family therapy technique have in particular included the prospects of a high acceptance rate (4), the freeing of the child and his or her family from the fear for the child's life, the immediate establishment of areas of child autonomy and parental control, the giving of hope and positive expectations to the family (52), and, ultimately, the reduction of symptoms (3, 33, 47, 50–54).

GROUP THERAPY

Rationale of Treatment

Group psychotherapy, like family therapy, has been advanced in order to address some of the presumed limitations of individual therapy for patients with psychosomatic disorders. Since a major concern is the special difficulty in entering a therapeutic relationship, two inherent changes in the manner in which the transference is manifested in group therapy in contrast to dyadic treatment are claimed to make it an especially suitable modality. The transference is split and its intensity is lessened due to the presence of several persons, including peers, with whom the patient interacts. In addition, the group format inherently offers the following distinct advantages to these patients: increased stimuli for participation and interaction, which can facilitate their involvement in the therapeutic process and the development of relationships; sharing of guilt, which allows their excessively rigid and archaic superego attitudes to be eased; and accessibility to others' intense feelings, which increases awareness of their own. The group format also offers greater interpersonal contact, which provides increased ego support for their typically weak egos and lessens isolation and the threat of separation; and, most critically, offers a greater opportunity to express emotions in an accepting peer atmosphere, which allows the displaced affect of these patients to be channeled verbally and directly, rather than only through somatic and autonomic avenues (56). Others have cited the group as an excellent medium for making psychosomatic patients "affect-conscious," that is, stirring up affects and emotions (6); the educational value of raising and answering critical questions, especially the increased transmission of information patients were unable to approach with their medical doctors (57–59); and the implicit gains of identification with persons having similar somatic experiences and attitudes (56), in particular, long-term survivors of illness (58).

Research Studies

A review of the literature reveals that the most consistent recipients of group psychotherapy include patients with asthma (probably the most generally investigated psychosomatic illness, with many forms of therapy) (52, 60–62), postmyocardial infarction (7, 58, 59, 63, 64), obesity (65–67), and chronic pain (6). Patients with these disorders have primarily been placed in homogeneous groups based on commonality of the illness entity or symptoms. Less typical formats have been the (late 1940s) spontaneous formation of heterogeneous psychosomatic patient groups comprised of members with different classical illnesses (56), and, as Wolff (68) noted, the heterogeneous combination of medical and nonmedical patients.

More than 25 years of clinical experience (1945–1970) with group psychotherapy for psychosomatic disorders have elicited a report of consistently impressive results (56). Sixty-six percent to 100% of the members improved; this included groups of chronic menopausal, ileostomy, and ulcer patients, including those with histories of unsuccessful individual treatment and severe underlying psychiatric disorders. The ileostomy and ulcer groups had the most successful outcomes and had maintained their improvement upon follow-up several years later. In addition, the all-female groups fared better than the groups containing men and women. On the basis of such results, proponents of homogeneous groups view the sharing of similar somatic symptoms and experiences as a decided advantage for positive outcomes (56, 63); however, the inclusion of nonpsychosomatic patients is often desirable in order to deemphasize the somatic issues that tend to be overly stressed in such groups (1).

The following studies have all been of homogeneous groups. In the study of asthma, Groen and Pelser's (60) long-term, controlled, and follow-up investigations of group psychotherapy for 200 patients are perhaps the most exemplary. These researchers used three comparison groups: symptomatic treatment only, ACTH, and group psychotherapy (male and female group therapy of 4- and 2-year durations, respectively). Despite the severity of diagnoses, group therapy was quite successful, both somatically and psychologically. Group therapy patients rated significantly higher than both control groups in all somatic outcome categories, including a significantly lower mortality rate; 73% of them were clinically cured, compared with 17% of the symptomatic treatment group and 29% of the ACTH group. Statistically significant Rorschach changes and informal confirmation by spouses and group leaders validated the positive psychological changes (69). Others have successfully treated not the patient per se, but the family members of asthma patients, with group psychotherapy (61, 62), especially concerning issues of sibling rivalry and family support

of the asthmatic child. While the parents definitely benefited from the group therapy learning process in terms of their awareness and ability to verbalize roles enacted within their own family constellations, there were no outcome assessments of the asthmatic children.

The sometimes subtle vicissitudes of the issue of psychological versus somatic improvement have also emerged in a variety of other studies, including the group treatment of obesity (65–67); patients with chronic pain, especially headaches (6); and the inpatient and outpatient management of myocardial infarction patients (7, 58, 59, 63, 64). With up to 2 years of group psychotherapy in the treatment of obesity, patients improved in their general adaptation, home life, and emotional well-being, but weight losses were at best minor (65–67). In the treatment of 56 pain patients using a combination of psychoanalytically oriented methods and encounter techniques, the group was considered an excellent medium for making the patients "affect-conscious" and in helping them perceive the interaction of their life difficulties, affective experiences, and somatic symptoms. However, neither the frequency of the headaches nor the magnitude of the pain appeared to be materially affected; and an increase in symptoms was observed as the patients became increasingly aware of the nonphysical origins of their problems (6).

Among the studies that have met with the most enthusiasm have been those involving postmyocardial patients (58, 59, 63, 64). The group sessions essentially served the function of an information gathering and sharing experience regarding issues of medication, nutrition, and physical activity, as well as attitudes toward family members, sex, and death. (This finding is at variance with findings from work with asthmatic patients, where it took approximately two years before the patients began to discuss psychogenic issues; they never discussed sex or fear of death [60].) There were no exacerbations of symptoms during the group sessions, and implicit gains included identification with long-term survivors of coronary illness, which naturally increased as the group members progressed in convalescence (63). In controlled studies (7, 64) the widest acclaim was for several short-term nonsymptomatic benefits such as directly answering patients' concerns, high acceptance of and adherence to a physical fitness program, and self-reports of increased self-confidence. However, longer term benefits such as fewer cardiac symptoms, increased return to work, and lower death rates were less conclusive. Ibrahim and associates' long-term, large sample controlled study (64) found no statistically significant changes in psychological factors (e.g., autonomy or understanding) or in physiological factors (e.g., blood pressure or cholesterol levels) during the entire follow-up period of 1½ years. However, there were several physical improvements of short-term duration and evidence of reduced hospital stay and increased survival rates.

As with other psychotherapeutic formats, the actual structural or process factors responsible for group therapy's outcomes have been minimally addressed. These factors include homogeneity of group composition (56), the maintenance of a "tolerant, educative attitude" rather than an interpretive one (60), and issues of short-term versus long-term, and psychological versus somatic, outcome criteria. Other research problems remain to be refined. Nonetheless, the educative value of group psychotherapy for psychosomatic patients and their families has been confirmed throughout the literature (7, 58, 59, 61–64), and psychological as well as physical results have been highly promising. In addition, in a controlled research study (6) the feasibility of the group as a therapeutic modality in terms of increased patient motivation and length of stay was "unequivocally affirmative" as indicated by an 84% acceptance rate, 69% attendance rate over 1½ years, and follow-up of 85% of the group. This augurs well for the future use of group psychotherapy as an alternative to, or adjunct of, other therapeutic regimes in the psychosomatic treatment armamentarium.

COMPARISON SURVEYS

Most psychosomatic outcome studies have at best researched a single disorder treated by a single psychotherapeutic modality, and cumulated work with any one disorder or modality has not been systematically generalizable to others. This has left the issue of comparative findings essentially unexplored. Although to my knowledge there is no single controlled psychosomatic study to date that comprehensively compares the effects of more than one psychotherapeutic modality, the following surveys shed some light on this essential, but as yet embryonic, area (8–11, 70).

Early collective findings in the use of psychotherapy for psychosomatic disorders contrasted the effectiveness of brief flexible psychotherapy and long-term psychoanalysis for a variety of disorders (8). The overall outcomes of both forms of psychotherapy ranged from poor to good, but when the outcomes were further analyzed according to illness, suggestive patterns emerged. Asthma studies showed consistently good results with either type of treatment and hypertension studies consistently poor results. Outcomes with rheumatoid arthritis patients were poor using brief flexible therapy, but promising using psychoanalytic treatment. For patients with hyperthyroidism brief flexible psychotherapy helped, but psychoanalytic treatment did not. However tantalizing the differential findings, they were faulted by methodological and research limitations.

Chalke's similar review format (9) for the subsequent 15-year period (1950–1965) revealed that psychotherapy had by then been applied to many medical conditions other than the classical psychosomatic disorders, e.g., chronic vasomotor rhinitis, migraine headaches, neurodermatitis, and spontaneous habitual

abortion. This review led to differential findings of another order: only for these newer psychosomatic categories was psychotherapy sufficient treatment; for the classical psychosomatic illnesses psychotherapy was significantly useful; but essentially as an adjunct treatment. This was particularly evident in ulcerative colitis and asthma patients, for whom psychotherapy was especially beneficial for the secondary emotional crippling and related personality and familial problems, although it did not necessarily materially affect the *physical* component, e.g., the asthmatic attacks.

These newer studies had the scientific advantage of having been conducted under somewhat improved controlled conditions, but definitive findings were not yet possible. In particular, the criteria for rating outcome were still admittedly vague. However, by locating instances of "psychological" versus "somatic" improvement that differentially occurred in different disorders, these studies inadvertently served to place the crucial question of outcome criteria in bolder relief, e.g., are there instances when therapy for psychosomatic disorders can still be considered viable treatment although the *somatic* component remains essentially unaltered? Although it is seemingly obvious, this issue has not been sufficiently addressed within the deliberative context of research designs.

A decade later, surveys of controlled studies covered a wide spectrum of new treatment modalities (and ills) (10, 11, 70). Although Malan's uniformly positive findings across several psychological formats and disorders were the most clinically and scientifically encouraging, they precluded the emergence of any specific patterns; too few studies of long-term follow-up were available (11). However, others (10, 70) uncovered some suggestive relationships between illness and treatment technique. Goldstein and Stein (70) concluded that systematic desensitization is differentially the most effective treatment for bronchial asthma, biofeedback for hypertension, autogenic training for migraine headaches, and psychotherapy for ulcerative colitis. Within the domain of the psychotherapies, psychoanalytically oriented treatment had the best differential outcomes in well-differentiated patients, and nondirective and supportive techniques fared best with symbiotic and regressed patients. Kellner's conclusions (10), based on a substantially greater number of studies, were more complex and cautious. Some disorders (e.g., asthma, ulcers, and migraines) appeared to be more amenable to psychotherapy than others (e.g., hypertension); some techniques fared better than others for different disorders (e.g., group directive techniques for peptic ulcers versus support and relaxation for muscular pain); and there seemed to be distinct individual and psychopathological differences in receptivity to different types of treatment.

Finally, my review, arranged according to therapeutic modality, serendipitously suggests that the differential pairing of disorder and treatment has often been implicit in the literature. It is not entirely clear whether this has occurred by accident or design. Thus group therapy techniques have been preferentially applied and reported with positive results primarily in the treatment of myocardial infarctions and migraines; family therapy techniques for diabetes, eczema, and anorexia nervosa; and individual therapy techniques for ulcerative colitis and peptic ulcer.

On the basis of such interesting but inconclusive findings, it is becoming clear that ultimately the efficacy of psychological interventions for psychosomatic disorders (as well as for other medical ills) will have to be based on careful comparisons of the outcomes obtained by different forms of psychotherapy in direct contrast with other therapeutic (psychological and medical) regimes.

CONSIDERATIONS FOR PRACTICE

In an assessment of the entire field of psychosomatic medicine in the 1970s, the development of increasingly effective therapeutic techniques was one of the major features noted (71). Most recommendations in this regard have pertained to *flexibility* of the therapeutic approach to psychosomatic patients, perhaps more so than would be required for psychoneurotic patients (1, 3, 23, 72). As has occurred in work with patients with personality disorders (23), borderline patients (72), and latent psychotics (3), most theorists and therapists in the field have ultimately relinquished, modified, or combined classical psychoanalytic techniques with essentially supportive approaches within the dyadic framework (1–3, 73), and/or have increasingly added to the therapeutic repertoire other than individual psychotherapeutic approaches, e.g., mother-child, family, or group approaches (3, 7, 33, 47–56, 58–67).

Wolff (1), who regards the main technical problem of such therapy as how to handle these patients' tendency toward regression, has suggested that the psychosomaticist must locate the middle ground between gratification and interpretation. Sperling (3, 33) cited psychoanalysis as her treatment of choice because it is capable of eliminating or resolving the psychosomatic patient's dependency needs, whereas supportive therapy merely shifts it onto the therapist. However, she felt that psychosomatic disorders may be treated by either therapy, particularly if one is aware of the assets and limitations of each. When using supportive therapy, guidelines include working with the patient on a conscious level only; providing insight by showing the connection between the occurrence of symptoms and affects without any interpretation of specific conflicts; helping the patient to direct his or her aggression so that it is not released solely through somatic symptoms; not dealing with transference phenomena; and not interfering with the patient's dependency relationship with the therapist or others in his or her environment (3). Others have concurred with these recommendations and other modifications of psychodynamic therapy, such as sitting face-to-face with the patient, not being silent, actively offering reassurance, and

seeing family members (2). It has also been suggested that the therapist interpret the patient's body posture and movements as descriptive of his or her affect, as an alternative to the direct interpretation of the emotion behind the affect (6).

More specifically, Alexander (57) has suggested that alternative approaches could greatly facilitate the clinical management of these patients, particularly when they are based on precise knowledge of the psychophysiological interaction and nuclear conflict of different types of patients. For example, ulcer patients, for whom accepting help from others mobilizes shame and guilt, react favorably to authoritative management; and the hypertensive patient's inclination to submit himself or herself to unrewarding and strenuous life situations that he or she inwardly resents can be useful in teaching the patient to avoid these types of stress-provoking circumstances.

While such suggestions have often provided the basic theoretical and technical orientation for approaching different types of psychosomatic patients, more recent recommendations are less contingent on the type of patient befitting a specific disease entity, nuclear conflict, or characteristic interaction. They have instead advocated major attention to the fit between patient and therapist (47), consideration of the nature of the patient's psychopathology (perhaps more so than the nature of the physical disorder) (10), and approaches that are not oriented to the illness but to the person and situation (68).

In a comprehensive study of therapeutic factors in the psychotherapy of ulcerative colitis patients, Karush and associates (42) found that the techniques of interpretation, support, emotional abreaction, and direct suggestion were variably effective with different patients, albeit with the same basic disorder. The more individuated patients did well with interpretation and abreaction, whereas the more symbiotic patients did better with support, suggestion, and graded abreaction. The latter also needed concrete verbal and behavioral evidence of their therapists' attachment and availability; and they were flooded by reactive anxiety about retaliatory punishment, and their symptoms intensified, after a cathartic outburst. Essentially, it was the fit between the patient's dependency needs and style of expressing them, and the therapist's response to them, that was particularly important to outcome. The best overall results were obtained by those therapists who were most flexible, that is, they could be active with some patients and passive with others.

It has been suggested that the overriding goal in dealing with all psychosomatic patients is the restoration of unity between psychic and somatic experience regardless of specific symptoms (68). Psychotherapeutic techniques would thus include the following recommendations: directly communicating to the patient a concern for his or her bodily symptoms by empathizing with his or her fears of being physically ill and allowing opportunities to express fantasies of illness; exploring life circumstances at the onset of illness; showing sensitivity to psychosomatic phenomena by linking psychic or feeling experiences with accompanying bodily sensations; and providing awareness of the link between life stresses and physical illness by shifting concentration from the illness itself to personal problems and painful feelings connected with the patient's life situations. Additional recommendations include deemphasizing physical symptoms that only reinforce the split between psychological and physiological events; recognizing the patient's need for physical contact (more so than sexual contact) and the way it is symbolically expressed to the therapist; and understanding transitional phenomena, especially in the patient's turning to his or her body or parts of it, or to the doctor, as transitional objects. Finally, the therapist must convey to the psychosomatic patient that he or she is continually available (although not necessarily for formal sessions). Psychosomaticists currently advocate person-related care and respect for the patient (68), upholding the central importance of the relationship between patient and therapist (42), and recognizing individual differences in receptivity to different treatment modalities (10). The major point of view is represented in the conclusion that "flexibility is the hallmark of effective treatment" (68, p. 245).

CONCLUSIONS

The overall state of the art of psychotherapeutic intervention for the medically ill has been generally marked by a paucity of systematic investigation and research. Although the data, format, and results of studies of psychotherapy for the medically ill have been highly variable, it is possible to draw some conclusions, albeit cautious ones, about the applicability of psychotherapeutic interventions to medical illnesses. Some patients with medical disorders may respond positively to psychological treatment, either physically or psychologically. Some medical disorders appear to be more amenable to psychotherapy than are other disorders. Some therapeutic modalities appear to be more effective than others. Some individuals appear to be more responsive to psychotherapy than others, especially in relation to the nature of their psychopathology, rather than their physical pathology.

This amalgam of results has profound implications for the future of clinical practice, and suggests the following requirements in future research studies:

1. The need for more comparative research in order to systematically evaluate all approaches, for example, the use of the same technique with different diseases and the use of different techniques for the same disorder.

2. The need for several detailed and consistent criteria of outcome in the psychological, social, and physical domains (in order to clarify findings that suggest psychological or social effectiveness but no physical change, or vice versa).

3. The need for longitudinal study and follow-up at various points, especially of several years' duration (in order to clarify and extend findings that suggest immediate positive or negative effects but no sustained results, as well as positive results from long-term treatment when short-term treatment does not suffice or even temporarily produces exacerbations of illness).

4. The need for more attention to the therapeutic process, not merely the endpoint or final outcome of therapy for the patient (in order to more precisely arrive at the mediating factors during the therapeutic endeavor that produce the particular results).

5. The need for greater specificity of the variables in each treatment situation that may influence the response to particular kinds of therapy (e.g., medical disease, nature of the psychopathology, patient/therapist factors).

It may then be possible to more critically explore and comprehend the role of psychotherapy in the treatment of medically ill patients.

Primary Prevention in Perspective

BY H. RICHARD LAMB, M.D., AND JACK ZUSMAN, M.D.

Discussion of primary prevention has been made difficult by lack of clarity of underlying concepts and assumptions. Is the purpose to prevent diagnosable mental illness or to prevent unhappiness and social incompetence? What are the implications of the assumption that societal stress causes mental illness? Is there a clear distinction made between major and minor mental illness? Except for a few specific conditions there is little evidence that primary prevention has been effective. The authors feel that research and program evaluation in prevention is sorely needed but should be funded separately and with discretion. Scarce mental health funds should not be diverted from direct treatment for this purpose.

PRIMARY PREVENTION of mental illness—actual avoidance of the occurrence of cases—has a powerful, almost irresistible attraction. Appealing slogans such as "Curing is costly—prevention, priceless!" and recognition that there will never be enough mental health professionals and facilities to treat all current and expected cases of mental illness in the United States have led to a search for and recently an enthusiastic acceptance of prevention as an alternative to direct treatment. However, given our present state of knowledge, is primary prevention of mental illness really possible? This crucial and obvious question too often goes unanswered or even unasked during discussions of program planning. The prominence that the President's Commission on Mental Health, the Mental Health Association, and the National Institute of Mental Health have recently given to prevention suggests that a review of the issues is needed.

Clearly, much of the discussion and debate over primary prevention is related to the fuzziness of the concepts and definitions underlying the issues. Unless care is taken to distinguish prevention of diagnosable mental illness from prevention of unhappiness, feelings of distress, or social incompetence, discussants will often be examining several different phenomena while thinking they are focusing on one. Unless it is clear what position the discussants are taking on the assumption—which is at yet unproved—that difficult life circumstances lead to mental illness, much of the debate must be fruitless because this assumption is basic to most (although not all) primary prevention efforts.

To be sure, some of the dedicated and sophisticated proponents of primary prevention recognize these distinctions (1), but all too often the cautious voices of these experts are drowned out in the excitement over the prospects of preventing substantial amounts of mental illness. Although some experts may be restrained in their claims for prevention, a good part of the general interest in prevention undoubtedly stems from the expectation of reducing the number of seriously ill, hospitalized, and disabled individuals—not simply because prevention may lead to a happier life for the average person. It is crucial that the distinction between preventing mental illness and preventing general emotional distress remain clear, not only so that we are clear as to what we are trying to accomplish, but also so that we are able to make intelligent decisions about priorities and the allocation of scarce funds.

Those concerned with primary prevention in the mental health field face first a complex problem of definition: the boundaries of mental health. When used by public health practitioners, the word "prevention" almost always refers to illness. Mental health services, on the other hand, usually deal not only with individuals with diagnosable illness but also with those who have no recognized psychiatric illness but who want help with their interpersonal problems and concerns of everyday living that cause them distress and unhappiness. Some mental health specialists go still further and feel that mental health services should be concerned with resolving basic social problems and with improving the quality of life. However, the cause and effect relationship between social conditions and mental illness is extremely questionable. It may well stretch both the definition of mental health and the public health concept of prevention beyond their useful limits to speak of mental health services and primary prevention in these areas. Moreover, the concepts, techniques, and expertise necessary for effective resolution of social problems are in no way related to those used by clinicians.

Concern with primary prevention in psychiatry has been with us for many years—at least since the 1920s. Interest has waxed and waned several times, but recently there has been an upsurge of interest again, counteracting the disillusionment with prevention of the early 1970s (2). The disenchantment in the 1970s

Received April 25, 1978; accepted June 19, 1978.

seems to have been a result of a combination of factors: the absence of any good evidence to confirm the effectiveness of primary preventive efforts; the recognition that primary prevention has been seriously oversold; and the shifting of interest to newer fads. Despite all this there are now again those who say that this is the time when primary prevention will come into its own. For instance, a national survey in 1974 among professionals and paraprofessionals in 515 community mental health centers and 193 state hospitals showed that respondents felt prevention was the third most critical current mental health issue, preceded only by children's services and adolescent services (3). The respondents estimated that in five years prevention would be the second most critical issue preceded only by children's services. Many articles, reviews, and books on primary prevention have recently appeared, most of which describe or advocate a particular type of preventive program. The final report of the President's Commission on Mental Health (4) recommended that increased funding be made available for primary prevention.

Despite this activity and concern, another critical issue remains—demonstrated effectiveness of primary prevention, or the lack of it. There seems to be general agreement that research has only begun to reveal something about the causes of most kinds of mental illness. Without knowledge of cause, primary prevention programs can only be shots in the dark. Moreover, recent research has increasingly suggested the operation of genetic and biochemical factors in the production of mental illness, and these factors are not targets of typical primary prevention programs.

THE SCOPE OF PRIMARY PREVENTION

Primary prevention must be distinguished from the other forms of prevention with which it is often confused. Public health practitioners divide preventive activities into primary, secondary, and tertiary (5); these terms were later adopted by mental health practitioners (6). Secondary prevention involves enabling people to regain their normal level of functioning and preventing further development of illness after its occurrence; early diagnosis and treatment is a sine qua non. Tertiary prevention involves preventing or reversing the sequelae of illness, i.e., disability. Secondary and tertiary prevention, despite their importance, do not have the glamour that primary prevention has, especially with regard to treating the major mental illnesses such as schizophrenia, nor do they offer the same potential for alleviating these disorders. For example, in the case of smallpox secondary and tertiary prevention do not hold out the same promise of widespread relief of suffering for a relatively small amount of effort that vaccination, the primary prevention, does.

Primary prevention has itself been subdivided into two categories—activities that promote health generally and thereby increase resistance to disease and activities that are aimed against the occurrence of specific illnesses.

In the area of mental health, most—if not all—successful primary preventive activities have been aimed at specific diseases. In contrast to the situation in large areas of physical illness, there is no evidence that it is possible to strengthen "mental health" and thereby increase resistance to mental illness by general preventive activities. Despite massive efforts to combat poverty (at least partly in the name of mental health), to increase social welfare and Social Security benefits, and to change the educational systems and methods of child rearing, there is no indication of a decrease in frequency of any of the functional mental illnesses. Nor is there obvious evidence that other countries with stronger social welfare systems and different child-rearing practices have different rates of mental illness. Thus, as far as we can see, the major functional mental illnesses (as well as the very frequent diagnosable minor illnesses) remain untouched by primary prevention in the sense of trying to strengthen mental health.

THE SHAKY UNDERPINNINGS OF PREVENTION

Many of the primary preventive activities currently proposed or in progress are based on theories that are far from demonstrated and no longer universally accepted in the field of mental health. In particular, we refer to the fact that most people who write or work in the field of primary prevention have a developmental orientation. They believe that later psychopathology, including the psychoses, is to be understood in terms of earlier life experiences. They "suspect that mental disorders are primarily a social phenomenon, that social factors drive people crazy. People most often become neurotic or psychotic in relation to other people" (7). As we see it, it is certainly true that the manifestations of mental illness and the social responses to mentally ill people are "in relation to other people." However, it does not necessarily follow that prevention can best be carried out in the social arena or that the principal cause of mental illness is societal stress.

This brings us to an important distinction that must be made between major mental illness, the psychoses, and minor mental illness, the neuroses and character disorders. Recent research, in particular the adoption studies of Kety and associates (8), indicates that major mental illness is probably in large part genetically determined and is probably therefore not preventable, at most only modifiable. Even that it can be modified is questioned by many and there is little hard evidence one way or the other.

When we leave the major mental illnesses we enter an area that is even less clear. There appears to be a greater likelihood that such minor mental illnesses as neuroses and character disorders are preventable by modifying societal factors that produce stress. Some

uncritically embrace this possibility as a "commonsense notion" (9). Others take an opposite point of view, again without hard evidence, that psychosocial influences have only a minor role, if any, in the causation of minor psychiatric problems. There are others, however, who take a middle course. For instance, Dunham (10) feels that

> There are certain forms of behavior, certain adult character disorders, certain patterns of nonconformity, certain symptomatic patterns that we label as psychoneuroses that may well have their roots in the character of our social life. But even here, the cause of these links is by no means conclusively established. We have numerous hypotheses, we have various perspectives and we have a certain amount of evidence attempting to link these psychological disturbances with the conditions of social organization. But there are many gaps in our knowledge here. These gaps will be particularly noticeable if we attempt to develop therapeutic procedures oriented with respect to the community that are supposed to cope with these mental ill-health conditions that have developed and are developing among certain persons in the community. (10)

The degree to which currently discussed primary preventive efforts can be effective depends on which of these hypotheses is correct. In the absence of strong evidence favoring social factors as the primary cause of neurosis, a major investment in primary prevention in the social arena is at best a hazardous venture.

As we have noted, there are those who strongly defend the relationships between environment and mental illness and some who have conducted studies to provide data in support of this hypothesis. The most notable and comprehensive of these studies have been those of Leighton and associates (11). They have shown that in the cross-sectional studies there is a relationship between the number of people who report symptoms commonly associated with mental illness and indicators of sociopsychological stress or, in their terms, "social disintegration." These indicators are weak and absent leadership, lack of recreational facilities, high crime and delinquency rates, widespread ill health, extensive poverty, cultural confusion, and a high frequency of broken homes. What these studies have failed to demonstrate is that there is a *causal* relationship between the particular stressful environmental factors under consideration and the occurrence of mental illness.

Other important studies (12, 13) have demonstrated that socioeconomic class is highly correlated with frequency of major mental illness; the bulk of the cases occur in the lowest class position, class V. Some have used this finding as evidence of a causal relationship between social class and major mental illness. Again, however, there is no evidence for such a conclusion (14).

There are several conceivable explanations for the statistical relationships found in these various studies. These include the possibility that the illness itself accounted for the person being in the stressful or undesirable situation (i.e., the hypothesis that schizophrenia accounts for one's class position rather than the class position's accounting for schizophrenia) or that the culture or sociopsychological environment influences not the occurrence of mental illness but the likelihood with which it will be reported, recognized, and labeled as such.

Aside from the fundamental flaw of a lack of good evidence of a causal relationship between societal factors and mental illness, there are a number of other problems in undertaking primary prevention that are almost as important. If it is granted for the sake of discussion that there is such a causal relationship, it remains to be demonstrated that the preventive efforts proposed will actually have a sufficient effect on the environment to change the occurrence of mental illness. Quite conceivably the work of a mental health consultant—or an army of mental health consultants—will never overcome the effects of such massive social forces and conditions as poverty, unemployment, and discrimination, any or all of which might lead to mental illness.

Again, if it is granted that environmental modification has an effect on mental illness, the question arises as to whether the types of preventive efforts that can be undertaken by mental health professionals are the most effective and appropriate ones to deal with the factors needing change. For example, assuming that one of the variables of concern for prevention is quality of education and/or student-teacher relationships, can a commonly prescribed preventive intervention—mental health consultation in the schools—actually have a significant effect on quality of education and/or student-teacher relationships? May there not be more powerful approaches to attaining the same result? Such activities, if they exist and if they fall outside of the jurisdiction of mental health professionals, are hardly likely to be called primary prevention, but their results are likely to be more to the point and their effectiveness greater.

In summary, then, much of primary prevention is based on theories that cannot be shown to account for most cases of mental illness and in particular for the major mental illnesses. Even if the underlying theory of environment as a cause of illness is accepted, there are still serious logical inconsistencies in the usual understanding of how primary prevention could work.

PRIMARY PREVENTION: PROVEN AND PROBABLE

There are primary prevention techniques in psychiatry that have been shown to be extremely effective. Psychiatric complications of syphilis and vitamin deficiency are seldom seen today in developed nations. Decreased rates of birth injury and improved prenatal care have lowered the incidence of major psychiatric problems resulting from congenital brain damage. Elimination of lead in house paint has reduced the

number of children suffering from organic brain syndromes, and control of industrial toxins has virtually eliminated "mad hatters" and other such problems.

There are newer preventive programs that undoubtedly are also effective in reducing the number of cases of illness. For instance, counseling prospective mothers not to delay pregnancy until the later childbearing years is likely to reduce the incidence of mongolism.

Other primary prevention programs show promise but have not yet been proven effective. In some cases the evidence in support of them is yet to be gathered. The present basis of such programs is theory, but this theory seems highly plausible and is generally accepted. Professional intervention and other programs for abusing parents such as Parents Anonymous seem likely to be effective in breaking the cycle of child abuse, which has been shown to be socially transmitted from generation to generation. Bowlby (15), Provence and Lipton (16), and others have demonstrated the deleterious effects of raising infants in impersonal institutions or without a consistent mother figure over a long period of time. Programs to replace institutions for homeless children with long-term high-quality foster care or adoption should prevent personality disturbance. With the mounting evidence of genetic influence on the occurrence of schizophrenia and manic-depressive psychosis, the appropriate use of birth control and genetic counseling should be effective in preventing the births of individuals who would be at high risk for development of these illnesses.

"PREVENTIVE" PRACTICES OF DOUBTFUL VALUE

Claims have been made that child-rearing practices will affect the likelihood of mental illness. These run the gamut from authoritarian to permissive, from bottle feeding to breast feeding, from mothers spending more time with their children to placing children in day nurseries while mothers find other outlets so they can appreciate their children and show more love to them on evenings and weekends. There is no evidence that any particular child-rearing practices affect the incidence of any of the mental disorders.

Mental health education, once a bright hope of community mental health, has in recent years been in eclipse, probably due in no small part to a book by James Davis titled *Education for Positive Mental Health* (17). After a thorough review of the literature, Davis concluded that in mental hygiene campaigns concerned with techniques of improving personal adjustment and prevention of mental illness, the important problem is not determining the most appropriate and effective means of communication and persuasion, but the fact that "mental health educators have little or nothing specific and practical to tell the public." For instance, even if environmental and situational stresses do play an important role in causing emotional distress, mental health educators still do not possess a body of knowledge that enables them to say more than, "Do not be poor or ignorant, and stay out of armed combat."

Crisis intervention has been considered a fertile area for efforts in primary prevention. To a large extent, however, crisis intervention is really secondary prevention, the provision of treatment services to people who are already in difficulty to enable them to regain their normal functioning and avoid further deterioration. It has been hypothesized that people are more amenable to learning more effective coping skills at times of crisis and that they will be better prepared to handle future crisis without further breakdown. Unfortunately, there is conflicting evidence that intervention will make a difference.

On the one hand, there is research evidence that it does not. Polak and associates (18) conducted a controlled study in which families who had experienced the sudden death of a family member were given crisis intervention services and compared at follow-up with two untreated control groups. Crisis intervention had not decreased the risk of psychiatric illness, disturbed family functioning, or social cost to the families. On the other hand, there are studies that have shown just the opposite. For instance, Raphael (19) showed that intervention with recently bereaved subjects decreased morbidity, compared with a control group, in terms of feelings of panic, excessive tiredness, weight loss, doctor visits for general symptoms, and diminished work capacity. Clearly, further research is needed to clarify the relationships, if any, between crisis intervention and primary prevention.

Many programs that have been called preventive programs are geared toward the development of competence in individuals. Although this is a worthy goal in and of itself, there is no evidence that developing competence prevents mental disorder. This point remains controversial, and the fact that many emotionally disturbed persons are educationally incompetent leads many to believe there is a cause and effect relationship. One often cited example is the Head Start program. Although there is no agreement as to the effectiveness of Head Start, there is some evidence (20) that this program can influence early school achievement. On the other hand, there is no evidence that this increase in achievement is related to a lowered incidence of mental illness in these individuals, although this conclusion is tempting.

Finally, there is a group of (often highly popular) activities commonly considered to be primary preventive whose effectiveness in preventing mental illness is, in our opinion, questionable to unlikely.

Foremost among these programs are a variety of measures undertaken by mental health agencies to eliminate socially undesirable factors in their communities, such as poverty, poor housing, inadequate educational services, violence, and unresponsive political systems. As Elaine Cumming (21) has pointed out,

"No one knows whether or not vile living conditions actually cause mental illness, but in a civilized society they should be found intolerable just because they are vile. All citizens, not just psychiatrists, should be appalled at them." There can be no doubt that the prevalence of symptoms associated with mental illness is higher among poor people and that rates of admission to state hospitals and of diagnosis of the major mental illnesses also are higher among this group. What remains to be unequivocally demonstrated, however, is that poverty is somehow causative. The situation is analogous to the relationships between social class, quality of environment, and mental illness, and the arguments are the same. For instance, people who are ill or on the verge of illness may gravitate toward poverty-stricken neighborhoods (downward drift).

Even if there were a clear demonstration of poverty as a causative agent of mental illness, this would not make poverty a condition to be dealt with by mental health professionals. Again, to quote Elaine Cumming, "There is a certain arrogance in someone who has been trained to heal the sick, imagining that he, therefore, has an expertise beyond that of any other thoughtful citizen in patching up the cracks in society." A more appropriate role for mental health professionals would be to emphasize the need for changes to those professional and political groups who have expertise and authority for implementing these changes.

It might well be asked why there is any need to be concerned with the definition of primary prevention and with the question of effectiveness of worthy social programs in preventing mental illness. If all agree that a program to eliminate poverty, for example, can only lead to an improvement in the quality of life and in any case is a good thing in itself, why raise these questions at all?

Why indeed! Mental health programs now and for the foreseeable future are operating in a world of shrinking resources. There is not enough money to go around, not even enough to support the basic mental health direct service programs that all recognize as fundamental and essential. To undertake programs that are expensive and quite likely not even preventive of mental illness out of funds allocated to mental health services seems to be a dangerously foolish gamble. If such programs are deemed socially desirable and politically popular, they should be supported from funds other than those allocated to mental health services.

CONCLUSIONS

A review of the field leaves only unanswered questions—many of them hidden from professional and public scrutiny by mountains of testimonials and hopes. Perhaps the foremost question is that of social policy—how much of scarce public funds and how much of our professional credibility are mental health professionals willing to risk on prevention programs that might be completely ineffective?

Unfortunately, we do not yet possess the techniques necessary to make primary prevention a reality except in a few limited areas. When allocating funds to preventive activities, therefore, we need to distinguish carefully among those programs which are proved, those which are not yet proved but seem well on the way to attaining this status, and those which are at best experimental. We need to make a distinction between programs preventive of diagnosable mental illness and programs aimed at prevention of unhappiness or social incompetence so that we can be clear as to what we are trying to accomplish and so that we are able to make informed and intelligent judgments about our priorities. We need to distinguish between prevention programs and programs designed to alleviate social and ethical problems. The latter group may well demand attention and support from mental health professionals, but primarily as concerned citizens and not as scientific experts. Prevention's appeal must be resisted by mental health professionals lest it become a glamorous rationalization for avoiding treatment of difficult, mentally ill persons, such as chronic psychotic, alcoholic, and addicted patients. Evaluation of basic and applied research and of programs in prevention is sorely needed, but it ought to be funded separately from direct treatment programs (22). Research and program evaluation, when properly carried out, is so expensive that such studies cannot be grafted on to existing programs as "minor" additions.

Finally, it seems that there is no easy way out of the problems that those of us concerned with serving the mentally ill face. Our difficult patients will not magically go away. We will simply have to struggle with each of the many discouraging if not overwhelming complexities and obstacles to overcoming mental illness and resist the temptation to go prospecting for the pot of gold at the end of the rainbow.

Early Review of Annual Meeting Papers

The *Journal* will continue this year its policy of early review of annual meeting papers. Final versions of papers that are ready before the Chicago meeting will be accepted for review. Do *not* submit your paper early if you anticipate substantive revisions after discussion at the meeting. Manuscripts should be submitted in triplicate, double-spaced throughout, and prepared in conformance with *Journal* style specifications, including length limitations. Papers written in "speech" format should not be submitted.

Please label the paper "Annual Meeting 1979, Final Version" and include on the title page the address and phone number of the corresponding author, and the number of words, tables, and figures. The cover letter should incorporate the copyright transfer statement described in "Information for Contributors."

Since the *Journal* has first refusal rights for annual meeting papers, it is necessary to obtain the Editor's permission before submitting a paper elsewhere.

If your paper will not be ready for review before the meeting but will be in final form at that time, bring three copies to Chicago and submit them to the session Secretary (submitting copies to the Press Office *does not* satisfy this requirement). Again, papers that are not ready for review should not be given to the Secretary.

If you have questions about this or other *Journal* policies, please stop by the *American Journal of Psychiatry* staff office during the meeting, and staff members will be pleased to assist you.

Relationship of Plasma Levels of Chlordiazepoxide and Metabolites to Clinical Response

BY KEH-MING LIN, M.D., AND ROBERT O. FRIEDEL, M.D.

The authors report on the relationship between the antianxiety effects of chronically administered chlordiazepoxide (CDX) and plasma levels of CDX and two of its metabolites, desmethylchlordiazepoxide (DMCDX) and demoxepam (DMX). Fifteen subjects with moderate to severe anxiety were studied in a double-blind, placebo-controlled, crossover design. Significant correlations were found between anxiety reduction and DMCDX and DMX plasma levels. No such correlation was observed between anxiety reduction and CDX levels. These data suggest that in chronically treated subjects, DMCDX and DMX have significant antianxiety properties which surpass those of CDX itself.

BENZODIAZEPOXINES have been generally accepted as effective in anxiety reduction (1) and are widely used in both psychiatry and general practice (2). However, the influences of drug absorption, distribution, metabolism, and excretion on the efficacy of these anxiolytic agents are still far from clear. In what is to our knowledge the only previously published report of this type involving chlordiazepoxide (CDX), Gottschalk and associates (3) studied the effects of a single 25-mg dose of this drug on anxiety; this study included evaluation of CDX blood levels. No placebo-drug difference in anxiety reduction was noted in the entire group. However, the 11 subjects who had CDX blood levels greater than 0.70 μg/ml 50 minutes after drug ingestion showed a significant placebo-drug difference in anxiety reduction, suggesting that a minimal blood concentration of CDX is required to obtain an antianxiety effect after acute treatment. Greenblatt and associates (4) evaluated the correlation between blood levels of CDX and its metabolite desmethylchlordiazepoxide (DMCDX) and behavioral symptoms in 10 asymptomatic healthy males after a single 25-mg dose of the drug. Self-ratings of "feeling spacey" at 1.0 hour after the dose were highly correlated with 0.5-hour blood levels of CDX plus DMCDX, but not with 1.0-hour blood levels.

A search of the literature revealed no reports of studies evaluating the relationships between the antianxiety effects of chronically administered CDX and plasma levels of CDX and its major metabolites. Since chronic administration is the most common dosage regimen of this widely used drug, such a study would seem indicated. Therefore, we have evaluated the relationship between the antianxiety effects of CDX and steady-state plasma levels of this drug and two of its metabolites, DMCDX and demoxepam (DMX), in 15 symptomatic unpaid volunteer subjects using a double-blind, crossover, placebo-controlled design.

METHOD

An advertisement was placed in the general news section of a large urban newspaper giving a clear description of the study. It included a 58-item Hopkins Symptom Checklist (HSCL) (5) as an initial screening instrument. Respondents with scores greater than 11 on the anxiety subscale of the HSCL (items 2, 17, 23, 33, 50, and 57) and less than 6 on four depression items (15, 19, 30, and 54) were contacted by telephone by the study nurse to elicit demographic information and a brief medical, psychiatric, and drug history, and to evaluate their willingness to follow the study protocol. After telephone screening, suitable subjects were referred to the study physician for the predrug evaluation, which included a medical and psychiatric interview, a physical examination, and completion of the Hamilton Anxiety Rating Scale (HARS) (6). Blood and urine samples were taken for electrolytes, glucose, liver-function tests, urinalysis, and drug screening. A tentative appointment was made one week later for the first session of the study pending results of laboratory studies.

Additional criteria for inclusion in the study were age between 18 and 50 years; a high-school diploma or equivalent; an HARS score greater than 12; the pres-

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received May 18, 1977; revised Jan. 5, 1978; accepted Feb. 10, 1978.

Dr. Lin is Robert Wood Johnson Clinical Scholar and Acting Instructor, Department of Psychiatry and Behavioral Sciences, University of Washington Medical School, Seattle, Wash. Dr. Friedel is Professor and Chairman, Department of Psychiatry, Medical College of Virginia, Richmond, Va. 23298. Address reprint requests to Dr. Friedel.

This study was supported in part by a grant from Warner-Lambert/Parke-Davis.

The authors thank Valerie Bloom, R.N., and Dr. Douglas Bowden for their support and contributions, and Dr. Gary Cox for his assistance in statistical analyses.

ence of sufficient symptoms so that, in the study physician's clinical judgment, treatment with an antianxiety medication was indicated; and willingness to return for subsequent visits. A signed consent form was obtained after the nature of the procedure had been explained to the subjects. Criteria for exclusion from the study were the presence of a significant physical impairment or medical disease; symptoms and signs indicating the history or presence of a borderline or overt psychosis, severe depression, or organic brain syndrome; the use during the previous month of any drugs, including marijuana, more than twice weekly, or of alcohol, more than one drink per day; pregnant women or nursing mothers; women of childbearing age not practicing reliable physical or chemical contraception; and a history of convulsive disorders, narrow-angle glaucoma, or allergy to benzodiazepines.

Fifteen subjects meeting the criteria were selected to participate in a double-blind, placebo-controlled, crossover study. Subjects were randomly assigned to receive identical capsules of either chlordiazepoxide hydrochloride or placebo; crossover was done at the end of 1 week. Subjects were instructed to return the bottle and unused medication at the end of the week, and a pill count was then recorded. The recommended dose of CDX was two capsules t.i.d. (20 mg t.i.d., 60 mg/day), with the last dose taken approximately 6 hours before each interview. If excessive sedation or other adverse effects were noted, the subject was instructed to take one capsule in the morning and at noon and two capsules at night (40 mg/day). If side effects persisted, the noon dose was to be omitted (30 mg/day). Subjects were advised to take at least 30 mg/day unless serious adverse effects persisted (this did not occur during the study).

Anxiety was evaluated by the following instruments: the 58-item Hopkins Symptom Checklist, a self-rating scale with subscales covering symptoms of anxiety, depression, obsessive-compulsiveness, somatization, and interpersonal sensitivity (5); and the Hamilton Anxiety Rating Scale, a physician-administered scale with items covering 14 symptom categories of anxiety, which can be divided into psychic and somatic subscales (6).

The severity of drowsiness was rated on a 4-point scale, with 0 = none, 1 = mild, 2 = moderate, and 3 = severe. The numerical values indicating the total magnitude of this side effect were computed by multiplying its severity by its duration in days (e.g., severe drowsiness lasting 7 days would give a score of 21).

Three interview sessions were conducted during the 2-week period of investigation, one before treatment and one at the end of each week of treatment. In all three sessions the subject first completed the HSCL, and then one of the investigators (K.L.M.) conducted the interview and rated the HARS. After the third (last) session was over, a discussion was held with the subject about his/her problems, and further treatment or referral was provided if necessary.

After each session, a urine sample was obtained for drug screening. At the end of the second and third sessions, blood samples were drawn for determination of drug plasma levels. Ten ml of blood were drawn from each subject into heparinized vacutainer tubes (Becton-Dickinson, East Rutherford, N.J.). Plasma was separated immediately and frozen. The Koechlin and D'Arconte (7) method as modified by Schwartz and Postma (8) was used for detection of CDX, DMCDX, and lactam metabolite (DMX). The sensitivity of this method for all three compounds is 0.2 μg/ml.

Differences between means were determined using Student's t test and the Wilcoxon sign test (9). Pearsons' product-moment correlation coefficients and Spearmans' rank-order correlations (9) were computed between variables such as symptom reduction, side effects, demographic variables, and plasma drug levels.

RESULTS

Seven men and 8 women, aged 28–50, completed the study protocol (see table 1). No subjects dropped out of the study. The mean reported daily dose of CDX for subjects during the drug week was 53.4 mg for women and 57.6 mg for men. Pill counts taken at the end of each week were generally in good agreement with the reported dosage for both placebo and drug with two exceptions (subjects 9 and 10).

Placebo-drug differences in anxiety levels as measured by the HARS and the HSCL for each of the 15 subjects are presented in table 2. Most subjects reported and were rated as having less anxiety after medication than after placebo. The placebo-drug differences in mean reduction in anxiety as measured by the total HARS (36%), the HARS psychic (39%) and somatic (31%) subscales, the total HSCL (24%), and the HSCL anxiety subscale (35%) were all statistically significant (see table 2) and were independent of any placebo-drug ordering effect.

Eight subjects reported drowsiness as a side effect (table 1). In these subjects it occurred more often in the drug than in the placebo week, with statistical significance approaching the .05 level ($t=1.98$). Other side effects were rare and transient, with 2 subjects reporting bitter taste after medication (subjects 3 and 12), and 1 each reporting thirst (subject 5), headache (subject 13), and questionable eyelid edema (subject 15), in the drug week. There was no relationship between the occurrence of side effects and rating scale changes, which ruled out the possibility of score assignments being contaminated by the presence of side effects. Age was found to be correlated positively both with drowsiness ($p<.05$) and with numbers of pills omitted ($p<.05$). There was also a trend toward a positive correlation between drowsiness and numbers of pills omitted ($p<.1$), suggesting a relationship between these three variables.

Apparent steady-state plasma levels of CDX and its metabolites (DMCDX and DMX) showed marked in-

terpatient variations, with standard deviations of 53%, 29%, and 58%, respectively (see table 1). Mean plasma levels of CDX and metabolites were significantly different; CDX levels were higher than DMCDX levels, which were higher than DMX levels. There was poor correlation between plasma levels of CDX and its two metabolites, DMCDX ($r=0.19$) and DMX ($r=0.16$).

TABLE 3
Correlations Between Symptom Reduction and Chlordiazepoxide and Metabolite Plasma Levels

Rating Scale	Correlation Coefficient (r)*

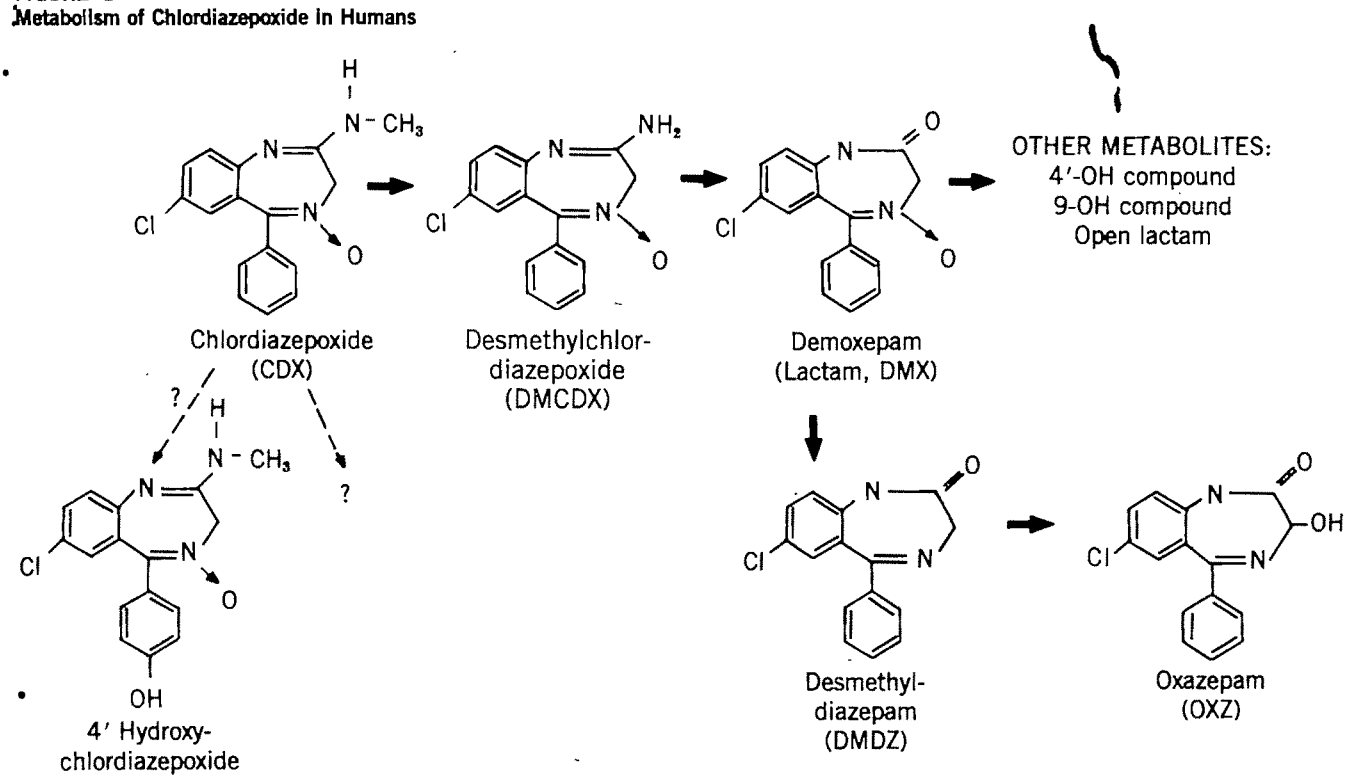
Anxiety	0.04	−0.24	−0.40	−0.14



*Nonparametric analysis with Spearman's rank-order correlation yielded identical results.
**$p<.02$.

The correlation between plasma levels of DMCDX and DMX was statistically significant (see table 1).

Correlations between symptom improvement (placebo-drug differences) and drug and metabolite plasma levels are presented in table 3. There was no correlation between antianxiety effect and plasma levels of CDX, whereas the correlations between DMCDX and total and somatic HARS change scores and between DMX and the somatic HARS change score achieved statistical significance. This correlation also exists between the total and somatic HARS change scores and the sums of DMCDX and DMX. Improvement in the HSCL rating scores did not correlate with plasma levels of CDX or its metabolites. The ratios of plasma levels of CDX to DMCDX, and DMCDX to total plasma levels were also tested against symptom reduction on both the HARS and the HSCL; these comparisons did not achieve statistical significance.

The plasma levels of CDX and metabolites do not manifest any significant correlation with sex, age, drug

FIGURE 1
Metabolism of Chlordiazepoxide in Humans

dosage as determined by pill count, and incidence of side effects.

DISCUSSION

To our knowledge this is the first reported evaluation of the relationship between anxiety reduction and plasma levels of chlordiazepoxide and its two metabolites, desmethylchlordiazepoxide and demoxepam, after chronic drug administration. The data indicate that the antianxiety effect of CDX after 1 week of administration is significantly correlated with plasma levels of its two major metabolites, DMCDX and DMX (table 3). In addition, there is a trend toward a positive correlation between symptom reduction and plasma total drug levels. There appears to be no suggestion of a correlation between anxiety reduction and CDX plasma levels. The significant correlation between DMCDX plasma levels and the total HARS and the HARS somatic subscale change scores, as well as a trend toward a correlation between DMCDX levels and symptom reduction measured by the HARS psychic subscale, suggests that DMCDX may affect somatic and psychic components of anxiety. This is in contrast to the relationship of DMX plasma levels with the reduction of only somatic symptoms of anxiety. The importance of CDX metabolites to therapeutic response with chronic treatment may be even more complicated, since it has been demonstrated that DMX is metabolized further to desmethyldiazepam, which is then metabolized to oxazepam (10) (figure 1), both of which are also known effective antianxiety agents. It would be important to also evaluate plasma levels of these metabolites in future studies of CDX.

These data may explain the failure of Gottschalk and associates (3) to demonstrate a significant antianxiety effect of CDX after a single dose of the drug, and a lack of correlation between CDX plasma levels and symptom reduction in their total sample. However, their finding of a significant antianxiety effect at plasma levels of CDX greater than 0.7 μg/ml does suggest that CDX itself has antianxiety properties, although possibly less than DMCDX or DMX. Our data in humans agree in part with studies performed in lower species. The antipentylenetetrazol activity of CDX in the rat appears to parallel brain levels of DMCDX rather than those of CDX (11). However, in the monkey, taming effects of CDX appear to parallel brain concentration of CDX better than that of the metabolites (12). Since other studies have demonstrated significant interspecies differences in the pharmacological effects of CDX and its metabolites (13), extrapolation of such data to humans is problematic.

The major therapeutic implication of these data is that one would not anticipate a rapid antianxiety effect after administration of CDX, since a significant amount of metabolism to its metabolites may first be required. This interpretation is consistent with the clinical observation of a delay in onset of action of CDX compared with diazepam. It may also explain the relative preference for diazepam over CDX by physi-

LIBRARY

cians and patients (14, 15) and its greater incidence of abuse (16). A rigorously controlled study comparing the temporal antianxiety effects of CDX, DMCDX, and diazepam and the relationship of these effects to plasma drug and metabolite levels would be most useful in clarifying this important point.

It may be argued that the lack of correlation of CDX plasma levels with antianxiety effect observed in this study is a function of the pharmacokinetic differences known to exist between CDX and its two major metabolites after chronic ingestion. Boxenbaum and associates (17) have recently reported that under these conditions CDX plasma levels vary more with time than those of DMCDX and DMX because of the shorter half-life of CDX. Therefore, this greater variability, which would be sensitive to the time lapsed between the previous dose and the taking of the blood samples, might mask a correlation between CDX plasma levels and pharmacologic activity. Although an effort was made in this study to ensure subject drug compliance and to obtain the blood sample approximately 6 hours after the previous dose, this is still a possibility. The high degree of intersubject variability of CDX plasma levels we have observed (SD=53%) and the lower variability of DMCDX (SD=29%) would seem to support this interpretation. However, the reverse is true for DMX (SD=58%), which correlates with antianxiety effect, and for total plasma levels (SD=35%), which do not. It would be important to control carefully for this possibly confounding factor in future studies.

There is no significant relationship between drug dosage and behavioral response. This is not surprising, since plasma drug levels are a function of drug absorption, distribution, metabolism, and excretion (18). Of these four factors, only the amount of drug absorbed is related to drug dosage. Most subjects reported that they took close to the maximum amount of drug prescribed (these reports were supported by pill counts), with a mean daily dosage of 55 mg (table 1). Therefore, it would seem likely that the intersubject variability in apparent steady-state plasma levels of CDX, DMCDX, and DMX is not related to differences in drug dosage but rather to interpatient differences in the pharmacokinetic processes noted above.

The blood levels of CDX reported probably represent steady-state levels, since most subjects had been taking the same dosage of medication for at least 4 days before the blood sample was taken. Steady-state levels are achieved in approximately four half-lives of a drug if it is administered at dosage intervals no greater than the half-life (19). Since the mean half-life of CDX has been reported to be 7 to 28 hours (20–22), steady-state levels probably had been achieved at the end of the drug treatment week. However, since the elimination half-lives of CMCDX and DMX appear to be considerably longer (17, 20, 22), it is possible that the plasma levels reported for these substances do not represent steady-state values, although they are probably very close (17). The lack of correlation between plasma levels of CDX and either DMCDX or DMX suggests that another metabolic pathway for CDX exists in man. For example, it is possible that hydroxylation of CDX to 4-hydroxy CDX also occurs (see figure 1). Although such a pathway has not been reported previously in man, it has been described in the rat (23). That DMX is the major metabolite of DMCDX is supported by the significant correlation between plasma levels of these two substances (table 1).

In this sample, plasma drug levels did not appear to be influenced by demographic factors such as sex and age. However, since the sample was limited to ages 28–50 and to subjects in good physical health, the lack of an age-related effect on plasma drug and metabolite levels should not be extrapolated to elderly patients. This cautionary note is supported by the recent data of Shader and associates (22), which indicate that absorption and metabolism of CDX are significantly reduced in the elderly.

We were not able to relate significantly the side effects reported in this study to plasma levels of CDX or of its metabolites or to total drug plasma levels. However, the correlation between age and the number of pills omitted and drowsiness suggests that older subjects are more sensitive to this side effect and that they reduced the intake of medicine to lessen its severity. This is consistent with the recent findings of Greenblatt and associates (24), indicating an increased incidence of residual drowsiness and other toxic symptoms in elderly subjects compared with younger ones treated with flurazepam. In our study, had subjects not been instructed to decrease medication in the presence of side effects, the incidence and severity of drowsiness may have been greater, and a positive correlation with plasma levels of CDX or its metabolites might have been achieved.

Papers on Hospitalization to Appear in *H&CP*

The 1978 APA annual meeting included a session titled Hospital Treatment of Emotional Disorders: Circa 1978. The group of timely and important papers presented at this session will be published in the February 1979 issue of APA's specialty journal, *Hospital & Community Psychiatry*.

The titles and authors follow:

"National Trends in Hospitalization," by Gerald L. Klerman, M.D.

"Intensive Psychiatric Care for Adolescents and Young Adults: A Model for Treatment and Evaluation," by John S. Strauss, M.D., T. Wayne Downey, M.D., and William H. Sledge, M.D.

"Short-Term Hospitalization and the Medical World," by Marvin I. Herz, M.D.

"The Hospital and Optimal Chemotherapy in Schizophrenia," by Theodore Van Putten, M.D., Philip R.A. May, M.D., and Stephen R. Marder, M.D.

"Hospitals in the 1980s: Service, Training, and Research," by Ira D. Glick, M.D., and William A. Hargreaves, Ph.D.

The Changing Role of Psychiatrists in Community Mental Health Centers

BY WALTER W. WINSLOW, M.D.

The community mental health center (CMHC) movement, largely conceived by psychiatrists to improve standards of mental health care nationally, appears to be going through an evolutionary phase in which there is decreasing utilization of psychiatrists and increasing utilization of other mental health professionals. The author discusses some factors that may have influenced this trend. In order to counter it CMHCs must become a recognized, essential, and respectable part of a pluralistic system of mental health care, and psychiatrists must be willing to assume their responsibility for involvement in all segments of mental health care, including the private and public sectors, in both leadership and clinical positions.

THE COMMUNITY mental health center (CMHC) movement could be seen as having its beginning in 1946 when President Truman signed into law the National Mental Health Act, creating the National Institute of Mental Health (NIMH). This was a significant milestone for mental health, for it marked the beginning of a unique national mental health program in research, education, and service.

In the early 1950s the leaders in psychiatry realized that much remained to be done, since there were still periodic exposés of "snake pit" care in the nation's state mental hospitals. As a result of increasing public concern, Congress passed the Mental Health Study Act, signed into law by President Eisenhower in July 1955, which authorized an appropriation to NIMH for a study and recommendations regarding mental health and mental illness in the United States. Out of this action came the Joint Commission on Mental Illness and Health, with a mandate to analyze and evaluate the needs and resources of the mentally ill in the United States and make recommendations for a national mental health program.

The Joint Commission study resulted in the landmark document *Action for Mental Health*, published in 1961 (1). This report urged an expanded program of services and long-term research. It attacked the concept of large state hospitals and proposed that they be converted into smaller regional intensive care centers. It recommended the development of community mental health centers, including emergency psychiatric services, for both chronically and acutely ill patients. The Joint Commission report also proposed massive financial participation by the federal government in the care of mentally ill patients, a responsibility that had previously fallen to the states. It outlined the principle of matching grants to facilitate federal involvement; it recommended that grants be awarded according to criteria of merit and incentive to be formulated by an expert advisory committee appointed by NIMH.

With the release of the Commission's report the stage was set for federal action. In 1963 Congress passed the Community Mental Health Centers Act (Public Law 88-164), which was signed into law by President Kennedy in October of that year. The original act authorized a total of $150 million in construction funds for a 3-year period, but financial assistance to communities for services was not provided until 1965 when Congress amended the act through Public Law 89-105 to provide grant funds for initial staffing costs for professional and technical personnel. These staffing grants were authorized on a decreasing matching basis for a period of 51 months, after which time it was expected that the CMHCs would have gained enough local financial support to continue operations without further federal funds.

In 1970, when it was realized that most centers could not become financially self-sufficient in 51 months, the duration of all staffing grants was extended to 8 years (Public Law 91-211). The legislative authority for new grants under the CMHC program expired on June 30, 1974, and was replaced by Congress with the 1975 amendments (Public Law 94-63), which authorized funds to create new CMHCs and to continue existing centers. The 1975 amendments were detailed and complicated, and regulations to implement this legislation often appeared not to support the intent of Congress, which was to have a community mental health service in every section of the country by 1985.

The community mental health center legislation—a "bold new approach" (2)—had a significant impact on the development of health care and contributed to what has been called "the third mental health revolu-

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977. Received May 6, 1977; revised Oct. 17, 1977; accepted Jan. 6, 1978.

Dr. Winslow is Professor and Chairman, Department of Psychiatry, University of New Mexico School of Medicine, 930 Stanford Dr., N.E., Albuquerque, N.M. 87131. He is also Director, University of New Mexico Mental Health Programs.

tion" (3). It modified the delivery of mental health services by deemphasizing institutionalization and transferring most of the mental health services to the community.

While the CMHC has expanded, the psychiatrist's influence and involvement in the CMHC seem to have diminished. It appears that other mental health professionals have assumed roles traditionally held by psychiatrists.

TRENDS IN CMHC MENTAL HEALTH MANPOWER

Psychiatric manpower in the United States has increased from 3,000 psychiatrists in 1939 to approximately 27,000 in 1975 (4). Much of this growth can be attributed to federal training monies made available through NIMH. The following data illustrate that psychiatrists are leaving CMHCs at a rapid rate and are being replaced by other mental health professionals.

On January 1, 1975, there were 434 federally funded CMHCs throughout all 50 states (5). This number had increased to 507 by July 1975 and to over 600 by 1977 (6). All 50 states have at least 1 CMHC, with California and Pennsylvania having 48 and 41, respectively, and Nevada having 1. The 434 CMHCs in 1975 employed 1,861 full-time equivalent psychiatrists, or about 6% of the total psychiatric manpower in the United States, serving catchment areas with a population of approximately 80 million people (7, 8).

Professional staffing patterns in CMHCs have shown a definite shift from 1970 to 1975. Table 1 reveals the relatively slow growth in the total number of psychiatrists and full-time equivalent psychiatrists employed in CMHCs from 1970 to 1975 and the more rapid growth in the number of psychologists, social workers, and other professionals.

Table 2 indicates that the average number of full-time psychiatrists per CMHC is diminishing, while the number of other mental health professionals is increasing. In 1970 there were 3.1 full-time psychiatrists per center; by 1975 this figure had dropped to 2.4. The decreasing number of full-time equivalent psychiatrists shown in table 2 probably also reflects decreasing part-time involvement, whereas the opposite is occurring for other mental health professionals. From 1970 to 1975 the number of CMHCs grew from 205 to 434 (over 100%), while full-time equivalent psychiatrists increased from 1,394 to 1,861 (approximately 50%). Over the same period the number of social workers increased more than 150% and the number of psychologists over 250%. The percentage of psychiatrists among total professional staff decreased from 25% to approximately 15%, while the other mental health professionals showed an increase.

The use of CMHCs as training sites for mental health professionals reflects similar changes. Fewer psychiatrists are receiving part of their training in CMHCs: 2.4 per CMHC in 1970 compared with 1.1 per CMHC in 1975. Psychology and social work professionals have increased their use of CMHCs as a training base over the same period. In 1970 there were 0.8 psychology trainees and 1.4 social work trainees per CMHC; by 1975 these figures had increased to 1.7 and 2.2, respectively.

TABLE 1
Number of Total Staff in CMHCs, 1970–1975*

Full-time equivalents	8.9	11.1	8.8	9.9	11.4	13.5

*Based on data from reference 5.

In another trend, fewer psychiatrists are directing CMHC programs. In 1973, 56% of all centers had psychiatrist directors or executive directors, compared with only 35% in 1975 (9, 10). A survey conducted in March 1977 indicated a further decline, with only 22% of all centers having psychiatrist directors (W.W. Winslow, unpublished data, 1977).

Over this same 5-year period the number of patients per CMHC increased more than 50%, including a large percentage of inpatients with major mental disorders. This implies that the psychiatrist, with his or her unique medical and pharmacological expertise, ought to assume a larger role in the CMHC.

DISCUSSION

The CMHC movement, largely conceived by psychiatrists to improve the standards of mental health care nationally, appears to be going through an evolutionary phase in which there is decreasing utilization of the psychiatrist and increasing utilization of other mental health professionals. From the beginning the CMHC approach was conceived to be multidisciplinary and multimodality; appropriate professional, technical, and paraprofessional manpower were to

complement and supplement each other. It was envisioned that psychiatrists would be significantly involved; initially this was the case, but the situation is rapidly changing, and in many CMHCs they now have little involvement.

The data clearly show a consistent trend away from the use of the clinical skills and leadership abilities of the psychiatrist, both in full-time and part-time participation in CMHCs. The use of centers for psychiatric residency training also shows a downward trend. With fewer psychiatric residents receiving part of their education in CMHCs and with fewer psychiatrists working in centers to provide adequate role models, it would follow that even fewer psychiatrists will develop an interest in CMHCs in the future. In my March 1977 survey, only 25% of the centers in the United States had an affiliation with a medical school, whereas 32% had an affiliation with a nursing school, 30% with a clinical psychology school, and 37% with a social work school.

What are some of the factors that may be influencing this trend? Initially, NIMH mandated that CMHCs must be directed by psychiatrists; this was later broadened to include most mental health professionals. A larger available pool of other mental health professionals, the comparatively smaller pool of psychiatrists with skills and interests in administration, and the relatively lower salaries needed to recruit other professionals may have been factors leading to the relatively rapid replacement of the psychiatrist director by other mental health professionals. Many psychiatrists who in the past preferred to remain actively involved in center programs are now finding professional activities outside centers more attractive and the milieu inside centers less engaging and are entering the private sector. Because CMHC psychiatrists have traditionally been involved in independent salaried settings, they find leaving full-time CMHC positions easier than do other mental health professionals who have not worked in such settings. As the impact of psychiatrists on CMHCs is diminished, they may often feel that they are being underutilized and relegated to the task of signing prescriptions and medical records. They may perceive increasing hostility in the program staff and less control over their environment, and they may therefore turn their energies elsewhere.

Medical schools have often been reluctant to sponsor and operate CMHCs. Centers are often organizationally complex, fiscally frightening, and administratively taxing to a department of psychiatry. Community boards and community groups must be listened to; goals and objectives cannot be developed unilaterally. Some CMHCs view the university as an elitist organization and as unable to sponsor or direct a relevant community mental health program. Sometimes this is the case; often it is not. However, this polarization may have a significant influence on universities and CMHCs loosening or severing their affiliations. If this is the case, medical students and psychiatric residents may well get the message that CMHCs are becoming increasingly less desirable settings for psychiatrists and psychiatry, and they will be even more inclined to avoid these settings when they begin their careers.

Possible solutions to this problem do exist. Medical schools in this country must become more involved with CMHCs, must tighten their affiliations whenever possible, and remain heavily committed. If this can be accomplished, residents will be reassured that psychiatrists do have meaningful roles in CMHCs and, one hopes, will later become associated with them.

Psychiatrists with administrative interests and abilities should be encouraged to become competent mental health administrators so that a larger pool will be available from which to select leaders of CMHCs. A widespread attitude that physicians make poor administrators must be confronted. Physicians without interest, training, or experience in leadership positions may make poor administrators, but those with interest, ability, and training prove to be very effective. Although many CMHCs are ably directed by nonpsychiatrist professionals, there is no reason to believe that they are inherently more capable. Universities and other educational institutions must make high-quality educational programs, fellowships, workshops, and seminars more readily available so that psychiatrists, during their residency or later, can add administrative and leadership skills to their areas of expertise.

If psychiatry is to reverse the trend of decreased involvement in CMHCs, the centers must become a recognized, essential, and respectable part of a pluralistic system of mental health care. The centers must take their appropriate place with other segments of the public sector and become integrated with and accepted by the private sector. This will not easily be accomplished because there is an increasing wave of distrust from the private sector, and perhaps vice versa, as the perceived territories of the CMHCs and the private sector begin to overlap. As long as CMHCs provided care only to indigent patients the problem was minimal, but since fee-for-service became involved CMHCs have frequently been seen as competitive and threatening to the fiscal survival of psychiatrists in the private sector. The psychiatric profession, inside and outside the CMHC system, must learn to work together if patients' clinical needs are to be met. Society will eventually demand that some form of high-quality mental health services be available to all, probably through some form of national health insurance that will almost certainly include CMHCs. If the assumption can be made that psychiatrists must be an integral part of any mental health delivery system, then the trend of decreased psychiatric involvement in CMHCs must be reversed.

Solutions may come from Congress, the American Psychiatric Association, or universities. Solutions may be forthcoming only with a major attitudinal change in the psychiatrists of this country. Only when psychiatrists are willing to assume their responsibility for involvement in all segments of mental health

care—the private and public sectors, in both leadership and clinical positions—will their return to CMHCs be evident.

Special Issue of *AJP* to Feature Depression and Alcoholism

A special issue of the *American Journal of Psychiatry* will be published in mid-April 1979. This issue, which will be distributed to all subscribers and is in addition to the regular April issue, will consist of a collection of articles on the subjects of alcoholism, depression, or both. Articles will deal with such topics as the treatment of depression with imipramine and ECT; bipolar illness: factors in drinking behavior; physical activity and plasma cyclic AMP in manic-depressive patients; childhood depression; life events at the onset of bipolar affective illness; psychiatric problems in women at alcoholic detoxification; lithium maintenance; efficacy of drugs, and psychotherapy in the treatment of acute depressive episodes; and life events, coping, stress, and depressive symptomatology.

Authors include David Avery, M.D., Jesse O. Cavenar, Jr., M.D., David L. Dunner, M.D., Ronald R. Fieve, M.D., Eric W. Fine, M.D., Evelyn L. Goldberg, Sc.D., John Hamm, M.D., Shirley Hill, Ph.D., Eleftherios Lykouras, M.D., Anthony Marsella, Ph.D., Roy Mathew, M.D., Jerome Motto, M.D., Irving Philips, M.D., Timothy Rivinus, M.D., Fred Steinberg, Ph.D., Marc Schuckit, M.D., Robert Belmaker, M.D., Martin Keeler, M.D., Paul Garfinkel, M.D., John Helzer, M.D., James Kocsis, M.D., Myrna Weissman, Ph.D., Alberto DiMascio, Ph.D., Gerald Klerman, M.D., Larry Ereshefsky, Pharm.D., Michael R. O'Leary, Ph.D., Steven J. Wolin, M.D., George J. Warheit, Ph.D., and Walter A. Brown, M.D.

Extra copies of the special issue will be available from the APA Circulation Department at a cost of $2.25 for domestic orders and $2.90 for foreign orders.

Impressions of Psychiatric Problems and Their Management: China, 1977

BY JOHN S. VISHER, M.D., AND EMILY B. VISHER, PH.D.

The authors, who visited the People's Republic of China in October 1977, describe the treatment methods used there, particularly in the Shanghai Mental Hospital, a 1,000-bed hospital for acutely ill patients. Psychiatric treatment there appears to be a blend of Western pharmacology, traditional Chinese medicine, and group therapy. The authors also speculate on the possible cultural sources of stress-related and interpersonal problems, provide a review of the literature regarding psychiatry in modern China, and outline the history of psychiatric treatment there.

IN OCTOBER 1977 we had the opportunity to visit the People's Republic of China. During our visit we spent a morning at the Shanghai Mental Hospital, visited general hospitals specializing in both Western and traditional Chinese medicine, saw neighborhood and factory dispensaries and clinics, and made inferences about the present status of mental health care in China. We also speculated about sources of stress in the population and the preventive techniques that may have a role in reducing the number of institutionalized mentally ill people in China.

PSYCHIATRIC LITERATURE

In recent years a small number of articles have described visits to China that were in some respects similar to ours. In May 1977 Leung and associates (1, 2) and Lowinger (2–4) reported on their visits to China. Leung and associates (1) concluded that mental health issues are managed through total support systems, usually involving family and work groups. Only the most serious illness comes to the attention of professionals. Lowinger (4) was impressed with the absence of evidence of neurosis in China and noted that such social and medical problems as drug addiction, alcoholism, prostitution, and venereal disease appear to have been virtually eliminated.

Received Jan. 26, 1978; revised June 5, 1978; accepted July 25, 1978.

Dr. John Visher is Chief, Adult Psychiatric Services, North County Mental Health Center, 45 Southgate Ave., Daly City, Calif. 94015. Dr. Emily Visher is a psychologist in private practice in Palo Alto, Calif.

In 1975 Walls and associates (5) wrote about a visit to China in 1973. One of these authors, L.H. Walls, is fluent in Mandarin, and the group was permitted to move freely without the constraints of translation difficulties. In 1973 David Ratnavale (6) also discussed a visit to the Shanghai Mental Hospital. His observations were in most respects consistent with our own.

A particularly valuable paper on the prevention and treatment of mental illness in the People's Republic of China was published in 1974 by D.Y.F. Ho (7), who is in the Department of Clinical Psychology at the University of Hong Kong. Dr. Ho has studied the history of psychiatry and the current status of the profession in China firsthand. He was impressed with the development of new methods to deal with emotional problems independent of traditional medical systems. He stated, "They have demonstrated what can be done when human resources are utilized to the fullest. They have shown that dynamic programs of treatment and prevention can be initiated when the whole society is mobilized, without having first to wait for more professionals to be trained" (7).

In 1973 Ruth Sidel (8) also discussed her experiences on two trips to the People's Republic. She pointed out that a major element in treatment there is the encouragement of psychiatric patients to feel that they are part of a force larger than themselves, namely, the Revolution. She said that patients are urged to take an optimistic view of their problems and to fight to understand and overcome their illness, not only for their own benefit but also for the sake of the Revolution.

HISTORY OF PSYCHIATRY IN CHINA

According to Ho (7), before Liberation, as the Chinese refer to the period before 1948, the mental health sciences were rudimentary; there were only a few small mental hospitals. Apparently there were only 4 in all of China, with a total of about 1,000 beds. The mentally ill were jailed, persecuted, or allowed to wander in the streets, where they often died of starvation and cold. After the Revolution, psychiatric care facilities and the number of psychiatrists expanded rapidly. In 1975, according to Walls and associates (5), there were about 60,000 psychiatric beds in China, located in 30 hospitals—2 for each province. Walls and associates also estimated that there were about 3,600 doctors specializing in psychiatry in China in 1975.

0002-953X/79/01/0028/05/$00.50 © 1979 American Psychiatric Association

A movement to humanize the mental hospitals, in some ways comparable to Pinel's work in Europe, took place between 1948 and 1958. Chains, isolation, and psychosurgery were largely eliminated. The hospitals began to use a combination of Western and traditional medical methods, emphasizing milieu and group experiences and including productive work as part of hospital treatment programs. An open-door policy was adopted, and efforts were made to "transform the hospital into a family-like institution so that patients can lead normal lives" (7). The hospital was seen as a battleground for the struggle against illness as well as a classroom for learning and practicing Communism. Family members were encouraged to become involved in the treatment, and great emphasis was placed on the patient's self-reliance. Patients were also encouraged to act as therapeutic agents for other patients (7). Outpatient therapy performed by psychiatrists or mental health workers does not exist in China as it does in the United States, although there are hospital-connected aftercare programs.

MANAGEMENT OF STRESS-RELATED AND INTERPERSONAL PROBLEMS

"Problems of living," personality disorders, marital conflicts, and interpersonal difficulties, which occupy so much of the time of outpatient mental health workers in the United States, are not seen in Chinese medical systems. These difficulties are handled by the extended family or by the work group, the neighborhood group, or the Revolutionary Committee.

It seems that people with physical or psychosomatic symptoms are treated in the regular medical system, in which patients can choose either Western medicine or traditional Chinese medicine. We heard reports that Western medical doctors might prescribe a tranquilizer such as diazepam, while traditional Chinese medicine would offer treatment techniques that include acupuncture with electrical current in the needles, moxibustion (a method of heating the acupuncture needle with burning wads of smoking incense), and "cupping," which involves external stimulation over painful shoulders or other joints. Traditional methods also include the use of herbal medicine. In this instance large packages of dried herbs or teas selected from more than 1,000 varieties of plants are carefully blended according to a prescription that takes into account the mythology regarding the emotional functions of each human organ.

The hospitals usually try to combine both Chinese traditional therapy and Western medicine whenever possible, but we learned that Chinese medicine is used more often for chronic illnesses and vague, nonspecific complaints. Hospitals varied according to the degree to which they used one or the other type of therapy. Often they used both simultaneously. "Cures" were attributed to Chinese medicine in medical conditions that were self-limiting or when palliation and calming effects were all one could provide, e.g., in a terminal cancer ward. As far as we could determine, no systematic effort is made to compare the different approaches.

SOURCES OF CULTURAL STRESS

It is interesting to speculate on possible sources of stress in Chinese society. Obviously, we were able to make only superficial observations in this area. In addition to the stress brought on by the fact that politics pervades every aspect of life in China, the recent changes in political structure, and changes in age-old systems and beliefs, we would add the stress of living so closely with others. Literally one is almost never alone in China. Crowds are everywhere, and large families live in cramped quarters like the two-bedroom, bath, and kitchen apartment we saw in Shanghai that housed 7 occupants who ranged from a 3-year-old child to an 82-year-old father-in-law.

Both premarital and extramarital sexual relations are illegal in China, and we were told there was no sex education aside from occasional high school hygiene classes. One wonders what is done with sexual tensions that have no apparent outlet until marriage, which is delayed to age 26 for women and 28 for men.

The competitive urges that certainly exist are expressed in sports and in working for the country. However, personal striving for advancement and personal wealth or security are considered no longer necessary because of the new social order. Workers strive for achievements that benefit the work group and result in increased production. "Model workers" are publicly acknowledged, and production records are posted so that everyone can see them. One holds his job for life and has little or no opportunity for change in either position or geographic location. One evening a worker who could speak a little English told us he hated his job. It would seem that the inability to change jobs except at the suggestion of a doctor would cause considerable stress.

Closeness between men and women, even in marriage, does not seem to be the norm. The government sometimes separates couples by means of geographically separate job assignments for long periods of time. The changed status of women, virtually all of whom work outside the home in neighborhood workshops or state factories from the time they graduate from middle school until they retire at age 50, may cause some stress. Husbands are expected to share the household chores and child care. According to our observations, many do so to an impressive extent. However, there may be some resentment. One man told us he did not want to marry because of the amount of time household chores would take. He preferred living with his mother, who did most of the housework.

Every Chinese person is a member of one or more overlapping small groups of 15 to 20 people. These groups spend 2 or 3 hours a week in meetings at which

the works of Marx, Lenin, and Chairman Mao and the latest principles of the Central Committee in Peking are studied in great detail. The discussion at these meetings often takes the form of "criticism-self-criticism" sessions, which we did not observe but which apparently are very much like leaderless encounter or therapy groups. The criticism is often very direct, and the person criticized is expected to respond with a frank confession of negative actions or thoughts that may have in some way contributed to the difficulties being discussed. There is much group pressure to conform to expected norms and to change deviant behavior and thoughts. A Chinese person is a member of a group first and an individual second.

The small group is obviously important from the standpoint of social control and communication of political ideas and guidance from above; for some individuals this may cause stress. On the other hand, the group can also offer a supportive and even therapeutic situation in which interpersonal conflicts, neighborhood problems, and job-related difficulties can be discussed. Feelings can be expressed and accepted, and the group rewards individuals for "good behavior." Neighbors and fellow workers do not stand aloof from the individual in trouble—as long as the individual accepts the group's guidance and conforms to the group ethic.

SHANGHAI MENTAL HOSPITAL

Severely mentally disturbed individuals are sent to mental hospitals in their geographic locale. We spent a morning at 1 of the 2 mental hospitals in Shanghai, a city of 11-12 million people. This hospital was established in 1958 and has 1,000 beds and 14 wards. The other hospital in Shanghai has approximately 1,200 beds and serves chronic cases only. The Shanghai Mental Hospital we visited treats acute cases only; the average stay is 2 or 3 months. Equal numbers of male and female patients are admitted, and there are no waiting lists for admission. The outpatient department handles about 500 outpatients every day, most of whom have been discharged from the hospital. The staff consists of 754 people and includes 86 doctors, 295 nurses, and 42 medical technicians in the X-ray department, laboratory, and pharmacy.

The hospital is a large complex of 3- or 4-story buildings set in a parklike compound behind a high wall. This layout is typical of factories and public institutions in China. We were impressed with how modern and clean it looked in contrast to other hospitals and public buildings we had visited. The wards were airy and light with long lines of beds in precise rows. We saw no personal articles or decoration of any kind in the patients' sleeping areas, although there were political slogans and schedules on the freshly painted walls. The furniture was very simple. One section at the end of each of several large unlocked wards we visited was for more disturbed patients. We saw a few patients in locked isolation rooms and 1 or 2 lightly restrained in beds. There were more staff on the disturbed wards. The staff were dressed in clean but unpressed white hospital coats and smocks and white surgical caps. Patients were dressed in ordinary street clothing; the women were dressed in more colorful clothes than the usual street clothing, which tends to be drab and plain. Nearly all of the patients were in the day rooms; they were not allowed in the sleeping quarters during the day. All of the patients were busy at activities that looked as though they had been arranged for our visit. Some were playing cards, some were assembling matchboxes or paper flowers. These tasks were work production projects from a nearby factory; we were told that the revenue from this labor reverted to the patient fund.

In the disturbed wards a few patients were posturing or gesturing, and nurses reacted quickly when a patient became excited. One young manic woman sang several songs for us in Chinese and then asked in perfect English, "Are you from Pakistan?" Another patient tried to join our group as we walked along, but she was spotted by a staff member who gently led her away. Although no patients seemed drugged or toxic, some seemed apathetic; almost everyone was quite docile and controlled. Doctors pointed out patients with diagnoses of depression, schizophrenia, and senile dementia in the disturbed wards. Most of the patients we saw were young. There were no children; we were told there is no need for children's psychiatric facilities any longer.

Relatives bring patients to the hospital with the help of their neighborhood or work groups. Each patient is given a thorough checkup, and a complete history is taken. (Compulsory involuntary admission of patients does not occur in China except in criminal cases.) The doctor makes a decision regarding hospitalization after he or she makes a diagnosis. In complicated cases consultation and/or a period of observation may be required before a diagnosis can be made. Cooperative patients are usually treated as outpatients. However, doctors told us that mental patients usually cannot cooperate because they do not admit that they have mental problems and refuse to take medicine. These patients are first taken to small wards where they are isolated because they are anxious and confused. The doctors use Western medicine to treat these patients. In 7-10 days they let them join in activities with other, less disturbed patients.

Eighty percent of the patients in the hospital are diagnosed as schizophrenic; these are primarily young people 14 years old and older. The number of young schizophrenic patients is steadily increasing, and the doctors are baffled as to the reason. They do not consider societal stress as a precipitant. Some patients are diagnosed as having "neurasthenia." These patients exhibit symptoms we would consider depressive, but they are usually treated as outpatients. Patients with epilepsy are also treated as outpatients unless they have an associated psychosis. Epileptics make up only

.1% of the total number of inpatients. Manic-depressive patients comprise only 1.5%.

Various treatment modalities are used. We observed four male patients being treated with acupuncture. They were seated around a small box providing low voltage current to wires leading to needles in their heads, necks, or limbs. In another room a patient was conferring seriously with a doctor and a nurse on a one-to-one basis. Elsewhere there was a group session with 20 or 30 patients and a nurse seated in a square, with one patient standing and telling the history of her illness and her delusions while the others held Chairman Mao's "little red book" in hands folded carefully on their laps. We also saw patients receiving their herbal tea.

We were told that there is a therapeutic milieu in which patients and staff are regarded as comrades in arms fighting in the struggle against mental disease. Patients and staff also work together to plan programs and accomplish the necessary hospital chores.

In the acute phase of illness Western medicine is used, and a combination of Chinese medicine and Western medicine is employed later. The doctors report that this combination has resulted in an overall improvement in effectiveness of treatment. When patients are hallucinating and highly disturbed, haloperidol, chlorpromazine, and perphenazine are used. Lithium carbonate is prescribed for manic patients. These medicines are combined with strong-voltage acupuncture twice daily. After 2 or 3 weeks, as symptoms improve, lower voltages are used and acupuncture treatments are less frequent. Combined treatments are given according to the judgment of the doctor, who emphasizes one modality or another. Apparently the hospital is not engaged in research to determine which modality works best, and there is no emphasis on keeping statistical records on the difference.

Special nurses organize patients into study sections, and each class lasts for about 1–2 weeks. The classes study Chairman Mao's philosophical works and articles written on how to handle "the contradictions among the people," which refers to interpersonal difficulties. The doctors also provide the patients some basic knowledge about psychosis so they can analyze their own case or course of disease. The patients are said to come to understand the reasons for their psychosis, which is seen as "subjectiveness and one-sidedness." The doctors believe that patients have arrived at wrong conclusions because they have not made thorough investigations. Knowledge of psychosis, therefore, helps the treatment and also helps patients know how to correctly handle the "contradictions" that might occur after they leave the hospital, thereby preventing recurrence of their illness. The hospital personnel feel that patients are harmed by being in the hospital too long and that patients should be discharged as soon as possible and looked after by society at large. After discharge the doctors think it is better for patients to be back at work even if they have not fully recovered and need to continue medication.

Doctors at the hospital stated that one of their important tasks was to help families and neighborhood groups understand the needs of the mentally ill and fit them into life at a level where they could continue to make a contribution to society. We heard of a case in which a fellow worker was assigned as a companion to someone who was psychotic. This worker lived and worked with the individual to help her conform to acceptable standards.

Hospital doctors often pay visits to patients living at a distance from the hospital who have been discharged to help them consolidate the effectiveness of the treatment and to reduce recurrences of illness. Outpatient visits are scheduled every 2–3 weeks following discharge, and doctors from the inpatient department will also visit the family at home if necessary. Before leaving the hospital, patients are given guidance about how to take medicines and how to manage their daily lives. When patients are considered able to return to work the doctors sometimes make suggestions to the leaders of the patient's work place for changes in schedules or jobs.

Since the Cultural Revolution (1966–1969), the hospital has been sending medical teams on regular tours through the factories and countryside to deliver medicine and medical care, to teach prevention of mental disease, and to train a number of barefoot doctors or paramedical personnel.

Patient care is paid for by the place where they work. The cost is 170 yuan a month, in contrast with the average rate of pay, which is 50 yuan a month.[1] However, patients pay the cost of their food in the hospital. For the first 6 months of hospitalization the patient's full work pay is continued, and after 6 months the patient receives 60% or 70% of his or her work salary, depending on seniority. Payment for nonworking patients is partly covered by the place of work of their spouse, and retired people receive free medical care.

Doctors in China receive less formal training than doctors in the United States. We were told that most of the doctors in the Shanghai Mental Hospital were trained in the Shanghai Medical College before the start of the Cultural Revolution in 1966. The length of training in medicine at that time was 5 years; now it is 3 years. Students in the medical college before 1966 studied the basic medical subjects and spent 2 weeks in a psychiatric hospital. After graduation, doctors who were assigned to work in the mental hospital were required to have 1 year of practice under the supervision and guidance of other doctors at the hospital. Under the shortened program, the study of psychiatry takes only 1 week, so after graduation doctors are required to have a longer period of hospital practice under supervision. Some doctors are selected from among the nurses with "rich experience"; these

[1]It is difficult to estimate the equivalent of 50 yuan in U.S. currency. The fact that a bicycle costs 200–300 yuan might provide a sense of its relative value.

nurses are required to have 1½ years of further study to become doctors.

COMMENT

Most acute cases of mental illness in China are effectively treated in large mental hospitals similar in many respects to our large state hospitals of 15 or 20 years ago. Treatment methods are a mixture of Western psychotropic medication and traditional Chinese medicine, including acupuncture, milieu, group, and activity therapy. Aftercare is the responsibility of hospital outpatient clinics, and community care by families and work groups provides continuing supervision and support. The medical care system offers care and treatment for physical illnesses related to stress, while life crises and problems of living are dealt with by the individual's neighborhood or work group.

Shared goals, values, and aspirations reduce the need to choose from among a variety of beliefs and lifestyles, but other personal, political, and cultural stresses apparently exist and result in emotional conflicts and symptoms for a number of individuals. However, the Chinese social experiment has resulted in an improvement in the quality of life for the vast majority of the Chinese people. Great progress has been made to provide all of the people with food, clothing, shelter, education, and low-cost or free medical care.

Differential Bonding: Toward a Psychophysiological Theory of Stereotyping

BY CHARLES A. PINDERHUGHES, M.D.

The author uses the concept of affiliative-affectionate bonding and the concept of differentiative-aggressive bonding to answer questions regarding the human tendency to stereotype. He states that the human processes of affiliation, introjection, identification, and affection appear to be psychophysiological elaborations of approach-seeking physiology and that differentiation, projection, and aggression appear to be psychophysiological elaborations of withdrawal-avoidance physiology. He also points out that some measure of stereotyping and paranoia may be necessary because differential bonding appears to be essential for adaptation.

STEREOTYPING IS UBIQUITOUS as a central component of group-related thinking and behavior. Among social scientists a stereotype is defined as a simplified and standardized conception or image invested with special meaning and held in common by members of a group. The prefix *stereo* is from the Greek word for "solid," and the word "stereotype" was originally applied to a process for producing solid metal printing plates from many separate pieces of type.

Allport (1, pp. 28–66, 106–137, 184–199) defined a stereotype as "an exaggerated belief associated with a category. Its function is to justify (rationalize) our conduct in relation to that category" (1, p. 191).

Stereotypes may be false or may contain some element of truth. They may be favorable or unfavorable. They may grow and persist in defiance of all evidence and may interfere with even the simplest rational judgments. All human minds must think with the aid of categories. It is not possible to differentiate objects or to handle the countless stimuli, impressions, relationships, and other experiences of life without doing so. Allport (1, pp. 20–22) indicated that the process of categorization has five important characteristics: 1) It forms large classes and clusters for guiding our daily adjustments. 2) It assimilates as much as it can to the cluster. 3) The category enables us quickly to identify a related object. 4) The category saturates all that it contains with the same ideational and emotional flavor. 5) Categories may be more or less rational.

Ordinarily, at two years of age children play with one another without regard for sex or race or other categories that they subsequently learn to use. Between the ages of four and seven they generally establish preferences for play with one sex. A favorable stereotype is applied to the preferred sex and an unfavorable one reserved for the other. Children who prefer girls may say they are gentle, kind, and loving and that boys are too loud, rough, and mean. Those who prefer boys may say they are active, enterprising, and stimulating and that girls are too quiet, uninteresting, or silly. In adolescence, youths who earlier had these preferences and stereotypes often reverse them. Learning and cultural factors play an important role in these developments. Ordinarily, association with one sex is facilitated more than association with the other sex.

During adolescence, if not earlier, many children in a heterogeneous society may start to show racial, religious, class, caste, and ethnic group preferences and to apply stereotypes. Learning and cultural factors play an important role in these developments as well. Association of members of the same group generally has been facilitated more than association between members of different groups. Parenthetically, it may be noted that wherever a specific group or stereotype is mentioned in this paper, the content may be applied equally as well to other racial, ethnic, religious, national, caste, or class groups and stereotypes.

CATEGORIZING AND STEREOTYPING

I have a number of questions in connection with these observations:

1. If we accept Allport's definition of a stereotype as an exaggerated belief associated with a category, why is the belief exaggerated when there seems to be equal opportunity for more realistic appraisal?
2. Why do people who take pride in their rational judgment hold so tightly to false beliefs in defiance of all evidence?
3. In the process of categorization, why does the mind assimilate as much as it can to the cluster, including some characteristics that are not present in the category?

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received May 5, 1977; revised Dec. 27, 1977; accepted Feb. 10, 1978.

Dr. Pinderhughes is Professor of Psychiatry, Boston University School of Medicine, Boston, Mass., and Assistant Chief, Psychiatry Service for Clinical Training, Veterans Administration Hospital, 200 Springs Rd., Bedford, Mass. 01730.

4. In the process of categorization, why is everything in the category saturated with the same ideational and emotional flavor?

5. Since sexual, racial, religious, class, caste, and ethnic stereotypes are not present at an early age but appear, intensify, or decline in the course of development, what relationship do they have to developmental processes and stages?

Although social psychologists, social psychiatrists, and sociologists have studied stereotypes in social and psychological fields extensively, they provide no answers to these questions. Psychoanalysts studying in psychological and social fields (2–7) have developed insight into the dynamic interaction of thoughts, feelings, and behavior associated with stereotypes. They have thrown light on the primitive and irrational mental processes through which all individuals pass and the persistence of these into adult life with dynamic variations in extent, intensity, and form under different conditions. Although they have not answered the questions, they have offered many hints that the answers to the questions lie deeper than we have tools to probe.

Although relatively well-developed psychoanalytic, psychological, and social psychological concepts of stereotypes have been produced, there has been virtually no development of psychophysiological concepts of stereotypes. We have very little ability to study the psychophysiology of a feeling and are virtually unable to study the psychophysiology of an idea. At psychophysiological levels we have no reliable information about the nature of stereotypes. In this absence I would ask what observations and ideas can aid those of us who suspect that part of the answer to our questions lies in somatic terrain.

My readings in biology over the years have been helpful in trying to answer this question. Studies of fish, birds, and animals led Lorenz (8) to perceive that animals which form attachments or bonds often show alternation of aggression and closeness and display aggression to one object and closeness to another. Closeness to a mate often follows aggression to a neighbor, and a bond to one may be enhanced by aggression to another. Lorenz wrote,

> The principle of the bond formed by having something in common which has to be defended against outsiders remains the same, from cichlids defending a common territory or brood, right up to scientists defending a common opinion and—most dangerous of all—fanatics defending a common ideology. In all these cases aggression is necessary to enhance the bond. (8, p. 190)

Lorenz conceptualized bonding in affiliative terms but not in terms of aggression. Biological research has also focused on attachments to territory as well as to mates and generally does not deal with aggressive behavior as bonding phenomena. Research on imprinting processes has also focused on development of bonds primarily in terms of following-seeking-affiliative behavior, as did Bowlby (9) and the Harlows (10) in their studies of attachment in humans and monkeys, respectively. Although approach-avoidance researchers seldom focus on bonds, Schneirla (11) noted that "biphasic mechanisms facilitating approach and withdrawal adjustments are present in all functional systems, from sensory to motor, in multicellular animals."

Schur and Ritvo (12) noted that Freud drew on his biological research experience in using withdrawal-avoidance concepts in his unpleasure principle and approach-seeking concepts in his pleasure principle. They noted that an inborn apparatus guaranteeing approach and withdrawal responses is necessary for survival. Freud's concept of links that become established between mnemonic images of perceptions and memory traces of body excitation (13) has aided the conceptualization of an organic relationship between body physiology and the external world. Schilder's work with the body image (14) and Deutsch's work with conversion process (15) made additional contributions to my conceptualization of the attachments human bodies develop to people, possessions, and ideas.

Human psychophysiological processes of affiliation, introjection, identification, and affection appear to be psychophysiological elaborations built on the bedrock of approach-seeking physiology. Differentiation, projection, and aggression appear to be built on the bedrock of withdrawal-avoidance physiology. Concepts of this kind are also consistent with Hess's division of body and behavioral organization into "ergotropic" and "endophylactic trophotropic" patterns (16).

DIFFERENTIAL BONDING THEORY

The above observations and ideas are consistent with psychosomatic and psychosocial concepts I have worked on since 1950. They were concisely expressed in 1971 (17) and in 1973 (18) as a series of hypotheses. Some of the hypotheses can be paraphrased as a theory of differential bonding or discriminatory physiological linkage that may offer a useful approach to my five unanswered questions.

Hypothesis 1

The physiological patterns that mediate approach-affiliative-affectionate behavior and those which mediate avoidance-differentiative-aggressive behavior are opposing physiological patterns that impose on all thinking and behavior a drive to dichotomize—to seek, join, introject, and make part of oneself on the one hand and to avoid, differentiate, and oppose on the other.

Hypothesis 2

The drive to dichotomize universally results in fluctuating physiology and ambivalence in early behavior with other persons and objects. Ambivalence can be

resolved only by differential physiological bonding. Affiliative-affectionate physiology is linked to mental representations of one object, while differentiative-aggressive physiological patterns are linked to mental representations of another. Such discriminatory physiological linkage results in greater constancy of relationships and of physiology.

Developmentally, these discriminatory physiological linkages become recognizable in diverse parts of the world by the eighth month after birth (19). The capacity to relate differentially to the familiar and the strange reflects early differential bonding. Subsequently, differential bonding may develop toward the images of any persons, groups, material things, sensory stimuli, body parts or processes, ideas, patterns, modes, or styles that may have representation in the CNS. (A physiological bond to the mental image of an object may be subjectively experienced as a physiological link to the object itself, although this is, of course, only an illusion.)

Differential bonding is generally incomplete, and reversion to ambivalence often occurs. This provides potential for a shift of bonds, for mourning and other separation processes, and for realignment and reorganization of relationships. Differential bonding may also show shifts with changes in the field with which a given image is associated. Two ethnically different Americans who relate as members of different groups when they meet in the United States may relate as members of the same group while they are engaged in a common interest, while they face a common adversity, or when they meet in a foreign country.

All object-directed behavior and all mental processes depend on the intricate dynamics of differential bonding. Compared with differential bonding in other animals, these processes in humans involve a greater range of images, greater capacity to bond and retain diverse images, greater capacity to bond images in various patterns, and greater capacity for sequential shifting of bonds from one image to another.

Each animal has its own characteristic potentials for differential bonding. These unfold and interact with experience in ways that define affiliations, aversions, friends, and enemies. Imprinting, grouping processes, territorial attachment, and mating behavior can be examined and formulated in terms of differential bonding, with affiliative and differentiative components differing in strength and in the amount of focus or diffusion.

Hypothesis 3

The object of the affiliative-affectionate linkage is aggrandized and the object of the differentiative-aggressive linkage is renounced as paired paranoid processes accompany the discriminatory physiological linkages. These processes are paranoid in the sense that they produce false beliefs based on projections that aggrandize objects of identification and denigrate renounced objects.

Paired dichotomous concepts, such as good-bad, right-wrong, in-out, high-low, front-back, and white-black, reflect the drive to dichotomize, but these regularly have one member of the pair preferred and the other devalued depending on the projections involving each member of the pair. Thus, differential projection is generally associated with differential bonding.

Hypothesis 4

All unambivalently constant relationships are basically paranoid, as objects of affiliative-affectionate bonds are aggrandized and objects of differentiative-aggressive bonds are denigrated.

Hypothesis 5

Groups are characterized by affiliative physiological linkages between group members or to common territory or common beliefs and by differentiative physiological linkages to common renounced targets. Nonpathological group-related paranoias are commonly found in groups. They bind together and socialize the group members and are to be distinguished from idiosyncratic pathological paranoias that isolate and alienate the believer.

Hypothesis 6

Behaviors disruptive to one's social group (such as sexual arousal, hostile discharges, excretory activity, and sudden loud noises) are discouraged in the group context. Images of these behaviors are likely to be renounced, repressed, and projected in social contexts. The association of mental representation of these behaviors with differentiative linkages facilitates their association with outsiders, reinforcing differentiative-aggressive bonding to outsiders and offering group members illusions of purity and superiority that reinforce affiliative-affectionate bonds between group members.

Hypothesis 7

Positive and negative feedback in life experiences determine what becomes associated with affiliative linkages and given high value and what becomes associated with differentiative linkages and given low value.

Hypothesis 8

Because of common linkages to affiliative physiological patterns, the more valued component of each paired relationship is associated with the more valued component of other paired relationships. Thus, the white, the high, the in, the front, the right, the head, the top, and the free are associated with one another in mental life. The dark, the low, the out, the behind, the left, the foot, the bottom, and the repressed are similarly associated in human minds because of common linkages to differentiative-aggressive physiological patterns.

Hypothesis 9

Once falsely positive or falsely negative attitudes and beliefs about people develop, relationships, social

structures, and the environment are modified wherever possible into a contrived reality that expresses, perpetuates, and seems to validate the false beliefs.

THE ANSWERS

On the basis of this speculative excursion into territory where psychology, physiology, and biology come together, it is now possible to construct some speculative answers to the five questions formulated toward the beginning of this paper. I will deal first with question 2: Why do people who take pride in their rational judgment hold so tightly to false beliefs in defiance of all evidence? The beliefs are organically linked to the body in the body image; to change them would thus introduce an instability in physiology that must be resisted. Clinicians evaluating somatic complaints often hear that some important trusted person had "deeply hurt" the patient or "caused great pain" by behavior that altered cherished beliefs and illusions. Denial is commonly used in attempts to ward off somatic discomfort associated with the perception of an unpleasant reality. Another answer to question 2 is that valued relationships with fellow believers would also be threatened by a change in belief.

Question 4 asked, In the process of categorization, why is everything in the category saturated with the same ideational and emotional flavor? In the course of relating in an unambivalent and physiologically stable way to any mental representation, including the mental representation of a category, it is necessary to relate either with affiliative-affectionate physiological linkage or with differentiative-aggressive physiological linkage, but not with both. Thus, categories linked in the body image to affiliative processes will be saturated with affiliative ideational content and affectionate emotional flavor. Categories linked in the body image to differentiative processes will be saturated with differentiative-aggressive content and flavor.

Questions 1 and 3 may be taken together: Why exaggerate beliefs when realistic appraisal is possible and why does the mind assimilate as much as it can to the cluster, including some characteristics that are not present in the category? If each of us has affiliative and differentiative twins in our physiology, minds, relationships, and outside world, we can expect that there will be aspects of our bodies, aspects of our minds, aspects of our relationships, and aspects of the outside world that we will value highly and have linked to affiliative physiological processes. Among the many such affiliative (introjected) categories with which we associate ourselves, easy transfers may take place from one to another because in the body image they are all united as a part of our acknowledged identity. There will also be aspects of our bodies, minds, relationships, and outside world that we will renounce, assign negative value to, and have linked to differentiative physiological processes. Easy transfers may also take place among the many such differentiative (projected) categories from which we renounce association because in the body image they are all united as part of the differentiated identity of outsiders. Thus, there is a psychophysiological tendency to impute to any category with which one identifies characteristics from other categories with which one identifies. There is also a twin psychophysiological tendency to impute to any category that one renounces and projects characteristics from other categories that are renounced and projected. Under these circumstances, exaggerated beliefs and the presence of characteristics that do not belong in the category can be expected regularly in the process of categorization.

When a group of people is excluded from social interactions as unacceptable, images of those people tend to be linked in unconscious thinking processes with those ideas, feelings, and body products which tend to be excluded from social interactions as unacceptable. Contact with the socially excluded people may be accompanied by a sense of something forbidden, bad, and possibly dirty or dangerous. Unconscious sexual, aggressive, and other repressed feelings may tend to emerge into consciousness in their presence, and stereotypes of the excluded people may contain all of these elements.

This brings us, finally, to question 5: What relationship does the development of stereotypes have to developmental processes and stages? Discriminatory physiological linkages occur at different rates at different times. They proceed more rapidly at points in development where psychophysiological instability has increased and can be corrected and stabilized by differential bonding. Thus, it occurs at a rapid rate in early childhood during resolution of the oedipal conflict, when mental representations associated with one parent are linked primarily to affiliative physiological processes and mental representations of the other parent are linked primarily to differentiative physiological processes. More rapid discriminatory linkage also takes place in adolescence in association with identity formation and participation in new grouping processes. Marked psychophysiological instability commonly precedes and perhaps activates increases in differential bonding and in the associated paranoia. Increased differential bonding and increased paranoia appear to help stabilize the psychophysiological instabilities that occur during healthy development as well as those which occur in acute pathological states. Stereotypes change with shifts in identifications and group relationships or as expressions of defensive operations against a shift in identity or relationships.

Data from many sources strongly support the conclusion that human beings are generally paranoid as well as sometimes wise. In fact, humans use their intelligence most frequently in support of their various nonpathological paranoias. The paranoias often gain expression in contrived relationships and in contrived social, political, economic, and educational structures. Stereotypes constitute one expression of them. These paranoias are not accessible to reason, and attempts to

alter them lead to confrontations and, often, to violence.

We should come to terms with the fact that healthy and normal people function with paranoid processes, especially in their group-related behavior. If we become aware that the processes with which we are involved are paranoid, we will be in a better position to cope with and manage them and to clarify what future generations need to do about them. Certainly the exploration of these processes in family therapies has helped many family members to better understand and better manage them. For example, I have described a family with frequent violent interactions (20) in which the hysterical wife had renounced control and discipline in her search for freedom of spirit and expression. She experienced her obsessional husband's disciplined and structured life as an attempt to stifle her and deprive her of life. The obsessional husband had renounced and warded off emotions and spontaneity. He perceived the hysterical wife as primitive, sick, uncontrolled, irresponsible, manipulating, and evil. Each marital partner was relating to a renounced and repressed aspect of himself or herself that had been projected on the other, who helped to maintain and reinforce the repressions and projections. Understanding this process and perceiving the mate as an aspect of self undermined the projection, reduced the conflict, and improved opportunities for better management.

It may well be that some measure of stereotyping and paranoia is necessary for the integrity of our bodies because differential bonding by means of discriminatory physiological linkages appears essential for adaptation and because stereotyping and paranoia go hand in hand with differential bonding. The biological process of differential bonding offers stability and certainty at the expense of objectivity and validity, producing a biologically mature organism that may know it is right even when it is wrong. This, in my opinion, constitutes the main source of bias in human thinking and behavior and the primary basis for social conflict.

In appraising these ideas we do well to keep in mind Freud's statement:

> The deficiencies in our descriptions would probably vanish if we were already in a position to replace the psychological terms by physiological or chemical ones. It is true that they too are only part of a figurative language; but it is one with which we have long been familiar and which is perhaps a simpler one as well.
>
> On the other hand, it should be made quite clear that the uncertainty of our speculation has been greatly increased by the necessity for borrowing from the science of biology. Biology is truly a land of unlimited possibilities. We may expect it to give us the most surprising information and we cannot guess what answers it will return in a few dozen years to the questions we have put to it. They may be of a kind which will blow away the whole of our artificial structure of hypotheses. (21, p. 60)

Freud's statements still hold true. He learned, as we should, that the ideas we hold now are very likely to prove false or at least biased. This does not deter some of us from speculating and taking steps to develop hypotheses that seem consistent with the existing data, although they are not yet testable.

Einstein's Creative Thinking and the General Theory of Relativity: A Documented Report

BY ALBERT ROTHENBERG, M.D.

A document written by Albert Einstein has recently come to light in which the eminent scientist described the actual sequence of his thoughts leading to the development of the general theory of relativity. The key creative thought was an instance of a type of creative cognition the author has previously designated "Janusian thinking." Janusian thinking consists of actively conceiving two or more opposite or antithetical concepts, ideas, or images simultaneously. This form of high-level secondary process cognition has been found to operate widely in art, science, and other fields.

ALBERT EINSTEIN was clearly one of the world's most creative scientists. Among his many accomplishments, the formulation of the general theory of relativity stands out as one of the most far-reaching scientific events in the modern era. As a new theory of gravitation, it embraced Newton's classic theory as a special case and allowed for extensive and grand conclusions about the universe as a whole. At the very least, the accomplishments and accumulated knowledge of modern astrophysics can be traced to this theory and the dramatic confirmations of its predictions in 1919 from data collected during a solar eclipse.

Because of his importance and the exalted nature of his accomplishments, many speculations have arisen about the roots of Einstein's genius and creativity (1–7). Much has been made of the rather remarkable but now generally known facts that Einstein learned to speak late, did not perform well in his early school years, and was not highly proficient in verbal skills throughout his life. Emphasis has been placed on the visual nature of his thinking, which he reported to his colleague Hadamard (8) and to Wertheimer (7). Because of Einstein's gentle and somewhat introverted personality and because visual thinking is often erroneously considered more primitive and more characteristic of childhood than verbal thinking, some have asserted that Einstein thought as a child thinks. This type of conclusion roughly coincides with many psychoanalytic formulations about creativity that postulate the regressive, primitive roots of creative thinking (9–11).

Tracing specific factors of creative thinking is highly complex and difficult, especially in science. Scientists rely so heavily on the contributions of their colleagues and predecessors and so much good scientific work derives directly from perseverance, memory, and logical capacity that it is hard to isolate and identify special kinds of thinking or skills in an individual discovery. Moreover, even when something is known about a scientist's personality, cognitive modes, and outlook, specific data are needed before it is possible to connect any particular personality factors or modes to a specific attainment or discovery. The assertions of childish, primitive thinking in Einstein's discoveries are especially based on surmise and speculation. Even the emphasis on visual and geometric thinking, plausible as it may be, derives only from Einstein's sketchy and general descriptions to Hadamard. As with most scientists, Einstein gave out very little information during his lifetime about the circumstances or specific sequences of thought connected with any of his attainments.

An important document has recently come to light, however. This document provides a direct and detailed account by Einstein himself of the actual thinking that led to his discovery of the crucially important general theory of relativity. Still unpublished in its entirety, it was written in Einstein's own hand in approximately 1919 and titled by him (in translation from the German) "Fundamental Ideas and Methods of Relativity Theory, Presented in Their Development." It was found after Einstein's death among his personal effects and includes an unusually explicit personal statement by a man whose writings are almost invariably scientific or impersonal. Even Einstein's autobiographical notes, written at age 67, consist primarily of an exposition of his theories (12).

The section I shall quote was subtitled by Einstein The Fundamental Idea of General Relativity in Its Original Form. Prof. Gerald Holton published other

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977. Received May 9, 1977; revised Dec. 1, 1977; accepted March 29, 1978.

Dr. Rothenberg is Professor of Psychiatry and Behavioral Sciences, University of Connecticut Health Center, Farmington, Conn. Address reprint requests to him at 139 Webb Circle, Monroe, Conn. 06468.

The author would like to acknowledge the Estate of Gladys B. Ficke, Ralph F. Colin, Trustee, for support of this research, and the Estate of Albert Einstein, Otto Nathan, Trustee, and Prof. Gerald F. Holton for the use of the Einstein material quoted. Professor Holton is responsible for the discovery of the Einstein material and for its translation.

translated versions and portions of these passages in 1973 (5) and 1975 (13). The entire document is in the Einstein Archives at the Princeton Institute for Advanced Study. The section I shall quote was translated by Professor Holton and was made available to me by the executors of the Einstein Estate, Otto Nathan and Helen Dukas. The section begins with Einstein's discussion of considerations involved in his discovery of special relativity theory, the theory he expanded and applied to gravitation in his general theory of relativity. These considerations involve a seeming discrepancy of interpretation arising from the Maxwell-Lorentz theory explaining Faraday's work on electromagnetic induction:

> In the development of special relativity theory, a thought—not previously mentioned—concerning Faraday's work on electromagnetic induction played for me a leading role.
>
> According to Faraday, when a magnet is in relative motion with respect to a conducting circuit, an electric current is induced in the latter. It is all the same whether the magnet moves or the conductor; only the relative motion counts, according to the Maxwell-Lorentz theory. However, the theoretical interpretation of the phenomenon in these two cases is quite different. . . .
>
> The thought that one is dealing here with two fundamentally different cases was, for me, unbearable [*war mir unerträglich*]. The difference between these two cases could not be a real difference, but rather, in my conviction, could be only a difference in the choice of reference point. Judged from the magnet there certainly were no electric fields; judged from the conducting circuit there certainly was one. The existence of an electric field was therefore a relative one, depending on the state of motion of the coordinate system being used, and a kind of objective reality could be granted only to the electric and magnetic field together, quite apart from the state of relative motion of the observer or the coordinate system. The phenomenon of the electromagnetic induction forced me to postulate the (special) relativity principle.
>
> When, in the year 1907, I was working on a summary essay concerning the special theory of relativity for the Yearbook for Radioactivity and Electronics I tried to modify Newton's theory of gravitation in such a way that it would fit into the theory. Attempts in this direction showed the possibility of carrying out this enterprise, but they did not satisfy me because they had to be supported by hypotheses without physical basis. At that point there came to me the happiest thought of my life, in the following form:
>
> Just as in the case where an electric field is produced by electromagnetic induction, the gravitational field similarly has only a relative existence. *Thus, for an observer in free fall from the roof of a house there exists, during his fall, no gravitational field* [Einstein's italics]—at least not in his immediate vicinity. If the observer releases any objects, they will remain, relative to him, in a state of rest, or in a state of uniform motion, independent of their particular chemical and physical nature. (In this consideration one must naturally neglect air resistance.) The observer is therefore justified in considering his state as one of "rest."
>
> The extraordinarily curious empirical law that all bodies in the same gravitational field fall with the same acceleration immediately took on, through this consideration, a deep physical meaning. For if there is even one thing which falls differently in a gravitational field than do the others, the observer would discern by means of it that he is falling in it. But if such a thing does not exist—as experience has confirmed with great precision—the observer lacks any objective ground to consider himself as falling in a gravitational field. Rather, he has the right to consider his state as that of rest, and his surroundings (with respect to gravitation) as field-free.
>
> The fact, known from experience, that acceleration in free fall is independent of the material is therefore a mighty argument that the postulate of relativity is to be extended to coordinate systems that are moving non-uniformly relative to one another.

The happiest thought of Einstein's life as described here was the formulation that provided the foundation for the general theory of relativity. From the exposition, it is clear that this "happiest thought" was his underscored (here italicized) phrase, "*Thus, for an observer in free fall from the roof of a house there exists, during his fall, no gravitational field.*" Einstein was not referring to the analogic thought in the immediately previous sentence because, in earlier paragraphs, he had made it clear that he had had in mind for some time the idea of an analogy between electromagnetic induction and gravity. The analogic thought, in other words, was the formulation of the problem, and the underscored idea was the solution. It is important to emphasize this because the exposition indicates many factors pertaining to Einstein's capacity to make this discovery, such as his full and complete knowledge of theories and facts, his extraordinary intelligence and lucidity, his passionate devotion to solving the problem, and his emotional involvement in the substance of the matter—seen in his statement, "The thought that one is dealing here with two fundamentally different cases was, for me, unbearable." All this is worthy of attention and analysis, but Einstein's creative leap of thought is discovered here for the first time clearly specified, and it is this thought—the happiest one of Einstein's life—which requires explication. The leap of thought Einstein described is an instance of a psychological process I have previously (in 1969 and 1971) defined, discussed, tested experimentally, and designated "Janusian thinking" (14–18).

JANUSIAN THINKING

Janusian thinking consists of *actively conceiving two or more opposite or antithetical concepts, ideas, or images simultaneously*, both as existing side by side and/or as equally operative or equally true. In order to clarify the creative nature of this type of thinking, I shall first briefly review the research that led to its discovery and then return to show how it is manifest in Einstein's dramatic formulation.

Janusian thinking was discovered through empirical

studies of the creative process consisting of extensive and intensive psychiatric research interviews focused on creative work in progress (19), analyses and reconstructions—both statistical and psychological—of literary creative processes of the past with predictions assessed in other types of research interviews (14) and experimental studies (17, 18). In the research interviews focused on work in progress, I regularly and systematically met with creative individuals over an extended period—usually months or years—and, in a collaborative effort (not a treatment or a psychotherapy), we explored the thoughts, feelings, fantasies, dreams, and events in their lives that were connected to the creative work they were engaged in at the time.

On the basis of these interviews, which total 1,665 hours to date, new experimental techniques were constructed and particular controlled experiments designed to elicit cognitive patterns were performed, both with the individuals who had participated in the interviews and with 149 other creative individuals and control subjects (17, 18, 20). Although differing criteria were used for assessing the creativeness of the individuals involved in the various researches, selection of individuals for the interview series was based primarily on two factors: high creativity ratings by peers and endorsement by society at large. For the creative writers and scientists who were my interview subjects, this meant roughly that they had achieved some major honor or award, such as the Nobel Prize, Pulitzer Prize, National Book Award, Bollingen Poetry Prize, membership in the American Academy of Arts and Letters, in the National Institute of Arts and Letters, in the American Academy of Arts and Science, or in the National Academy of Sciences, and that they were considered highly creative through an objective survey of their writer and scientist peers.

The term "Janusian thinking" is based on the Roman god Janus, whose multiple faces (two, four, or six) (21) were turned in several opposite directions at once. In apparent defiance of logic or matters of physical impossibility, the creative person formulates two *or more* opposites or antitheses coexisting and simultaneously operating, a formulation that leads to integrated concepts, images, and creations. This form of thinking, apparently unique to creative people, plays a constant role in diverse types of creative processes. From the reports of my subjects and from other documented sources, it clearly operated during the creation of poems, novels, plays, paintings, or sculptures, and it operated during the creation of new scientific theories and creative leaps of thought connected to very important scientific discoveries (20). Occurring at crucial moments during the process of creating, usually at the moment of inspiration, this form of thinking has effects that are not always overtly manifest in the final product. The Janusian formulation, in other words, is often a crucial step or way station that later undergoes a good deal of transformation and revision.

Before I describe the revisions and transformations as well as the functions of Janusian thinking, it is important to note that many untransformed Janusian formulations are clearly manifest in some of the great creations of the world. In religious creations, for instance, there is the Yin and Yang formulation of the oriental Taoist religion: two opposite and universal forces or principles operating together as a single force. Nirvana and Samsara are the dominant unified principles of Buddhist theology: Nirvana, the end of the cycle of rebirth, is opposed to and simultaneous with Samsara, the endless series of incarnations and reincarnations of living things. In the Middle East Zoroastrianism, the major religion of the vast Persian Empire, had as its basic tenet the simultaneous presence from the beginning of all things of the twin but opposite gods Ormazd, the god of light and goodness, and Ahriman, the god of darkness and evil. The precepts and descriptions in various aspects of Western theology of a simultaneous operation of God and the Devil, insofar as they are theological creations of the human mind, are also direct manifestations of Janusian formulations.

In philosophy simultaneous opposition and antithesis are manifest in the pre-Socratic conceptions pertaining to Being and Becoming, Nietzsche's Dionysian and Apollonian principles, Kierkegaard's belief by virtue of the absurd, and Sartre's representation of Being and Non-Being. In psychology there are Freud's formulations of the conscious operating together with the unconscious and the theory of the dually functioning but opposed instincts of sex and aggression. Direct manifestation of simultaneous opposition is probably most apparent in the poetry produced by great creators throughout the world and throughout the ages. Many major poets and critics, including William Blake, Samuel Taylor Coleridge, Cleanth Brooks, Robert Graves, Amy Lowell, Robert Penn Warren, Allen Tate, and John Crowe Ransom, have emphasized that poetry is fundamentally based on elements of opposition or a close relation, paradox.

All these examples suggest the workings of Janusian thinking in diverse types of creations, but my evidence is not based merely on consideration of these final created products. It is derived from experimental data and empirical observations of the constant use of this type of thinking in the achievement of creative ideas. For instance, plagued all his life by the suicide of a roommate in his youth, a suicide apparently precipitated by the roommate's wife's infidelity, a great playwright came to realize that the suicide was also motivated by guilt over a simultaneous but opposite wish—the man had wanted his wife to be unfaithful. The formulation resulting from this realization—the idea that his former roommate had both wanted and not wanted his wife to be unfaithful—instigated the writing of one of this playwright's most highly esteemed plays, and the idea directly influenced that play's structure and substance (14). Another noted playwright decided to write a comedy shortly after his father's death. He structured this highly successful play around characters who were both living and dead at the same time.

These characters were not to be represented as ghosts but as lost persons struggling to survive and to understand what had happened to them (20). Another subject of mine, a novelist, during an early phase of thinking about a novel's plot, conceived of a revolutionary hero as responsible for the deaths of hundreds of people but killing only one person with his own hand, a person who had been kind to him and whom he loved. Much of the subsequent novel became an elaboration of this early idea.

One subject, who was a poet, conceived the central image of a poem when he thought of horses as both human and beasts simultaneously, that is, horses were beasts but they lived human lives, they were not human and were human at the same time (20, 22). Another poet, walking on a beach, came on some rocks and thought: the rocks are heavy, they are weapons of violence but, *at the same time*, they feel like human skin. This inspiration led to the construction of a poem concerning the relationship between sex and violence in the world. That sex and violence have much in common was an immediate formulation at the time of perceiving the antithetical qualities of the rocks. For an example from painting, a careful analysis of Picasso's drawings and the successive stages of his creation of the great mural *Guernica* leads to the conclusion that his earliest conception, visually formulated, was of a woman (holding a torch in the completed mural) looking both inside a room and outside onto a courtyard at the same time (20). In context, all of these creative constructions involved high-level, conscious, abstract thinking. As a psychological process, Janusian thinking is a complex, nonprimitive form of cognition.

EINSTEIN'S CREATIVE COGNITION

The sentence following Einstein's underscored and happiest thought is, "The observer is therefore justified in considering his state as one of 'rest.' " Adding this, Einstein clarified the essence of his thought. As he surely knew, the observer falling from the roof of a house is in a state of motion, he is moving during his fall. However, as Einstein conceived it in this formulation, the observer is simultaneously in a state of rest; the observer is thus *in motion* and *at rest* at the same time. This was Einstein's observation about a physical circumstance that allowed him to modify Newton's theory of gravitation so that it would fit into relativity theory. It imbued the "extraordinarily curious empirical law that all bodies in the same gravitational field fall with the same acceleration" with a "deep physical meaning." From the formulation that an observer in free fall is both at rest and in motion at the same time, Einstein was able to postulate the relativity of motion in coordinate systems. Thus, the crucial step in the development of the general theory of relativity, Einstein's creative leap, was a formulation of the opposite states of motion and rest operating simultaneously, an instance of Janusian thinking.

That Einstein knowingly formulated a condition of simultaneous antithesis is clear from the discussion in context. In ordinary experience, falling or being in motion and being at rest are completely antithetical. He therefore devoted several sentences to explaining the particular considerations allowing the moving observer to—as he states twice—"consider his state as that of rest." As Einstein knew, it was a rather shocking and dramatic breakthrough.

The complete development of the general theory of relativity depended on the previous conception of the special theory, as Einstein here made clear, and that theory depended, as Gerald Holton has shown (5), on the direct and indirect influence of Maxwell, Lorentz, Mach, Poincaré, and Föppl as well as important scientific, sociological, and philosophical currents of the time. Other factors included Einstein's enormous capacities for deductive and inductive logic, for combining and separating categories and symbols, and for intense concentration as well as his profound understanding of the rubrics of science and mathematics. As Einstein made clear in this passage, however, the key creative step consisted of finding a way to connect gravitation to relativity on the basis of empirical or physical reality. This key step was formulated all at once as a simultaneous antithesis.

As an instance of Janusian thinking, the formulation was not developed through a stepwise weighing of physical or conceptual alternatives, such as drawing cumulative inferences from a series of observations or deriving conclusions directly from a theory. Nor, as is intrinsic to a dialectical process (dialectical and Janusian thinking are not the same), did Einstein consider the opposites or antitheses in systematic fashion in order to synthesize or combine them. Although he may have engaged in such systematic thinking about the problem at other times, he stated he was working on a summary yearbook essay when he conceived the entire idea.

There was nothing primitive, childlike, or regressive in the creative leap. Absent from the account are any suggestions of an altered state of consciousness or the intrusion of ego-alien material. There is nothing to suggest primary process material appearing in consciousness, no sudden idea followed afterward by critical and logical evaluation. Einstein was fully aware of the logic and reality of the issue at the moment he had, in his words, his "happiest thought." He did not magically conceive of the equivalence of opposites. Visual thinking, which Holton (5, 13) and others (7, 8) have emphasized, and imagery seem to have been present. The idea of a person falling from the roof of a house suggests a visual conception. Rather than the primary process visual imagery emphasized by regression theories of creativity, however, Einstein's probable visualization in this case very likely involved another type of high-level creative thinking (Homospatial thinking), which I have described extensively elsewhere (22).

Einstein's account also clearly conveys both the aesthetic orientation and emotional investment ("The

thought that one is dealing here with two fundamentally different cases was, for me, unbearable.") connected with his scientific thinking that has been emphasized by Holton (5). An interest in economy and simplicity and what Holton has described as a sensitivity to asymmetry and an interest in symmetry seem to play a general role. Janusian thinking is related in an instrumental and critically facilitative way to these general factors. As it is extensively operative in aesthetic creation, as it has definite and specific connections with emotional sources and emotional goals (15, 20), and as simultaneous antitheses or oppositions are intrinsically symmetrical, Janusian thinking is a more primary creative factor than the general ones. Holton's observations are important; aesthetic goals operate ubiquitously in scientific creation. Looking for economy or rejecting asymmetry or being emotionally invested are not, however, the same thing as deriving the particular formulation of simultaneous antithesis that provides key conceptions and dramatic creative leaps.

In its fully worked-out form, the general theory of relativity presented what physicists today consider the principle of equivalence of gravitation and inertia. According to this principle, there is no way to distinguish the motion produced by inertial forces—acceleration, deceleration, centrifugal forces—from motion produced by gravitational force. In blind-flying in an airplane, for instance, it is impossible to separate the physical sensation of pulling out of a dive and that of executing a steeply banked turn at high speed; one cannot separate the effects of inertia from those of gravitation. In both cases blood is drawn away from the brain and the body is pulled down heavily into the seat. The fully worked-out theory, moreover, gave a picture of the universe as a four-dimensional space-time continuum, a construct that changed previous conceptions such as that of the universe as an island of matter in a sea of space. Revolutionizing science, philosophy, and man's view of the nature of physical experience, this construct is the basis for all modern cosmological conceptions. The theory not only allowed for predictions about deflections of the light of stars seen in a solar eclipse, it explained an observation about the behavior of the planet Mercury that had not been accounted for by Newton's laws. It provided a means of dealing with high speed velocities and intense gravitational fields, and it provided an understanding of the shape and size of the universe. Much elaboration, deduction, and calculation went into the development of the entire general theory of relativity, and there has been much empirical testing and conceptual elaboration since it was first constructed. However, as Einstein's exposition now makes clear, the key thought allowing for the formulation, the creative leap giving his incomplete ideas a physical basis and bringing them together in a meaningful formulation, was the specific conception of opposites operating simultaneously—an observer being in motion and at rest at the same time. Such a formulation is a cardinal instance of the creative cognitive process of Janusian thinking.

The cognitive process I have described is not the same as that reported by other investigators. It is not at all merely a manifestation of Guilford's "divergent thinking" (23), Koestler's "bisociation" (3), DeBono's "lateral thinking" (24), or Mednick's formulation of the bringing together of remote associates (25). It is a directed thought process involving active formulation rather than association or bisociation. Moreover, it involves active espousal of specifically antithetical or oppositional entities rather than only divergent or "lateral," unrelated, or remote ones. Nor is Janusian thinking an illogical or prelogical process. In distinction to schizophrenic thinking or the thinking in dreams, for instance, it is a logical postulating of what, on the surface, seems illogical. It is not a form of primary process thinking nor does it derive directly from the unconscious. The creative person actively brings together opposites and antitheses as a means of formulating scientific and other problems, initiating and facilitating aesthetic tasks, creating theories, making discoveries, and constructing works of art.

As seen in Einstein's description, during the creative process the creative person is in neither a trance nor an altered state of consciousness, nor is there any indication that unconscious material erupts directly into consciousness. This is not primary process or free association material brought into consciousness by suspension of secondary process thinking and/or logical and critical judgment. Nor is it correct to say that Janusian thinking consists of unconscious or preconscious material appearing in consciousness during an altered state and then later subjected to logic and critical judgment. Critical assessment and logical elaboration are always necessary to construct and articulate a full theory, discovery, or work of art, but, as Einstein's description again makes clear, the creator is also fully logical and capable of full critical judgment at the moment of the Janusian formulation. Janusian thinking is a form of secondary process cognition. Creative individuals are fully aware that the elements of their thought would be, in a particular context, antithetical, but they engage in what may be called a logic-transcending or "translogical" leap of thought.

1978 Anniversaries

BY GEORGE MORA, M.D.

The author recalls 1978's anniversaries of events and individuals prominent in the history of medicine, psychiatry, and psychology and examines their practical and theoretical contributions.

1578

William Harvey was born in Folkestone, England. After receiving a thorough classical education at the King's School in Canterbury and Caius College in Cambridge, Harvey studied in Padua, Italy, where he graduated in medicine in 1602. Back in England in the same year, he married the daughter of the King's personal physician. In 1607 he was elected Fellow of the College of Physicians, in 1609 became associated with St. Bartholomew's Hospital, and in 1618 became physician to King Charles I, with whom he developed a close relationship. For 40 years, beginning in 1616, he held the Lumleian lectures on anatomy and physiology at the College of Physicians. Greatly upset by the Civil War, he remained faithful to Charles I. He died in 1657.

Harvey is universally known for his discovery of the circulation of the blood. His discovery, based on solid experimental research, was described in his famous *De Motu Cordis* (1628). Among his other writings are the *Prelectiones* (notes on physiology and pathology related to his Lumleian lectures) and *Exercitationes de Generatione Animalium*, in which he expressed his belief in the theory of epigenesis.

An acute observer of human psychology, especially of women (undoubtedly fostered by his gynecological practice), Harvey followed contemporary views, based on the Galenic tradition, on the knowledge of the nervous system. In the field of psychiatry proper, he anticipated concepts of modern psychosomatic medicine. In *Exercitatio de Motu Cordis et Sanguinis* he wrote that "every affection of the mind that is attended with either pain or pleasure, hope or fear, is the cause of an agitation whose influence extends to the heart." Elsewhere he related the observation of a

> strong man, who having received an injury and affront from one more powerful than himself, and upon whom he could not have his revenge, was so overcome with hatred and spite and passion, which he yet communicate to no one, that at last he fell into a strange distemper, suffering from extreme oppression and pain of the heart and breast . . . and in the course of a few years . . . became tabid and died.

Harvey also described the physiological signs of fainting related to emotions and stated that

> in almost every affection, appetite, hope or fear, our body suffers, the countenance changes, and the blood appears to course hither and thither. In anger the eyes are fiery and pupils contracted; in modesty the cheeks are infused with blushes; in fear, and under sense of infamy and shame, the face is pale but the ears burn as if for evil they heard or were to hear; in lust how quickly is the member distended with blood and erected!

Harvey's psychological insight is particularly evident in regard to symptoms of hysteria. "Women occasionally become insane through ungratified desire, and to such a height does the malady reach in some, that they are believed to be poisoned, or moonstruck, or possessed by a devil." Having stated that the uterus is a most important organ, and brings the whole body to sympathize with it, he said,

> How dreadful, then, are the mental aberrations, the delirium, the melancholy, the paroxisms of frenzy, as if the affected person were under the dominion of spells, and all arising from the unnatural state of the uterus. How many incurable diseases also are brought on by unhealthy menstrual discharges, or from over abstinence from sexual intercourse when the passions are strong!

Harvey also left a beautiful description of a case of "hysteric" pregnancy:

> a young woman . . . who experienced in her own person all the usual symptoms of pregnancy; after the fourteenth week, being healthy and sprightly, she felt the movement of the child within the uterus, calculated the time at which she expected her delivery, and when she thought, from further indications, that this was at hand, prepared the bed, cradle, and all other matters ready for the event. But all was in vain. Lucina . . . tutelar deity of childbirth . . . refused to answer her prayers; the motion of the fetus ceased; and by degrees, without inconvenience, as the abdomen had increased so it diminished; she remained, however, barren ever after.

Received July 31, 1978; revised Oct. 16, 1978; accepted Oct. 25, 1978.

Finally, in the case of an 18-year-old girl who had "lost the sense of feeling in the external parts of her Body," obviously on a hysteric basis, Harvey "advised her Parents (who sent her not thither out of poverty) to take her home, and provide her a Husband, by whom, in effect, she was according to his Prognostick, to many Mans wonder, cured of that strange Disease."

1778

Jean Jacques Rousseau died in Ermenonville, France. Rousseau's mother died at his birth in 1712 in Geneva. Having received an uneven education from his unstable father, he fled Geneva and was helped for many years by Mme. de Warens, toward whom he developed a strong attachment. After having held several jobs, he became involved with an ignorant servant girl, by whom he had five illegitimate children, all of whom were sent to a foundling home. In the meantime he became acquainted with some of the leading representatives of the French Enlightenment. His early writings reveal his dissatisfaction with the failure of scientific progress to improve the condition of mankind. His two main works, *Le Contrat Social* and *Émile,* appeared in 1762. After the latter work was burned in Paris by the Catholic authorities, Rousseau accepted an invitation from philosopher David Hume to make his home in England in 1765. Shortly thereafter Rousseau quarreled with Hume and began to show evidence of emotional disturbance. He returned to France and spent his last few years in Paris.

Basic to Rousseau's thinking was his rejection of the cult of reason advocated by the Enlightenment as leading to happiness; in contrast, Rousseau advocated a return to the state of nature. Hence, Rousseau issued his proposal that social life be based on a contract allowing maximal freedom to the individual. A necessary postulate for this is the development of mature individuals through a proper process of education. It is obvious that Rousseau's educational ideas were closely linked to his social goals.

Four stages of education are clearly defined in the four parts of *Émile*. In the first, from birth to 2 years, the child begins experiencing things; in the second, up to 12 years, the senses develop under the influence of pleasure and pain. In the third stage, from 12 to 15 years, the child learns not in an abstract, but in a concrete, way; in the fourth, from 15 to 20 years, the child develops rationally and acquires the ideas of values and religion.

Thus for the first time it was clearly stated that childhood should be studied with its own criteria rather than from the viewpoint of the adult. Childhood should not be seen as an age of imperfection, since it had its own uniqueness and adequacy based on feelings and instinctual needs. As Rousseau put it: "Nature wants children to be children before being men. . . . Childhood has its own ways of seeing, thinking and feeling." Moreover, he felt that a truly positive education began only when the child became aware of his or her relationship with other people.

Although written with a passionate style and presented in an uneven way, *Émile* had a tremendous impact not only on education but on the newly developing field of psychology as well. It was only at the beginning of our century that Rousseau's idyllic concept of childhood was substantially modified by the psychoanalytic emphasis on sexuality and aggression as basic characteristics of childhood. It is likely that Rousseau's revolutionary views were influenced by the unhappy circumstances of his childhood and by the vicissitudes of his life.

Christian Friedrich Nasse was born in Bielefeld, Germany. Proving at an early age to be highly intelligent, he showed an interest in music and modern languages. After studying at several universities, he received his medical degree in Halle in 1800. In 1815, after several years of general practice, he accepted the position of professor of medicine and chief physician at the hospital of the medical school of Halle. In 1819 he was called as clinical professor of medicine to the newly established University of Bonn, where he remained for the rest of his life. There he directed his energies toward two main goals: the care and treatment of patients and the training of students according to the then-modern direction of experimental research on animals, work in the laboratory, and bedside teaching. A prolific writer, he published books and articles on various aspects of medicine. Among his publications on psychiatry is the volume *On the Treatment of the Mentally Ill by Non-Physicians* (1844). He founded and directed the *Journal for Psychological Physicians* (1818–1826), *Annals of Anthropology and Pathology and Therapy of Insanity* (1830), and the *Journal for the Diagnosis and Treatment of Pathological Mental Conditions* (with Jacobi, 1838). He died in 1851.

At various times Nasse called his system psychophysiology, psychosomathology, and anthropology—names that emphasize the unity of the personality. He viewed psychosis as entirely dependent on a physical condition; as mind and body are indissolubly united, it is impossible to speak of mental disorders in the strict sense of the term. He also assumed a critical stance toward mechanistic and spiritualistic, and monistic and dualistic attitudes. Under the influence of the philosopher Herbart, he attempted to build a psychology based on mathematical foundations and void of philosophical postulates. His principles of clinical medicine were based on direct observation of the patient, assessment of environmental factors, and formulation of the individual diagnosis. In the Clinic for Mental Disease, which he opened in Bonn in 1819, he created a small community of patients, teachers, nurses, and students. For him, the psychiatrist should be an "anthropological physician" as, indeed, he was himself: a specialist in welfare medicine, clinical matters, teaching, and legal issues.

Along with other representatives of German organicistic philosophy of psychiatry (Reil, Friedreich, Jacobi), Nasse was opposed to the so-called "mentalists" (Heinroth, Ideler, Groos). He denied the existence of prenatal psychological influences and viewed all deductions of psychologists on the infantile psyche as pure fantasy. For him, the etiology of mental disorders had to be found in disorders of the various organs of the body, especially the brain. Yet under the influence of Herbart, he accepted the notions of "threshold of the unconsciousness" and, consequently, of repression and inhibition. He was also interested in the study of dreams and somnambulism. In the practical handling of the mentally ill he was eclectic and open-minded, making use of dietetics, limited means of restraint, psychological influence, and occupational therapy.

1878

Claude Bernard died. Born in St. Julien (Rhône, France) in 1813, he received essentially a humanistic education. After working as an assistant pharmacist for some time (and unsuccessfully as a writer), he studied medicine in Paris, where he became assistant to François Magendie. Under his influence Bernard became involved in experimental physiology, as indicated by his medical thesis on the role of gastric juices in nutrition (1843). He developed the notion of "physiological autopsy," a technique aimed at isolating the properties of tissues and organs with the help of chemical substances. Among his most important discoveries in the field of neurophysiology during the succeeding years were the etiology of diabetes, the constricting and dilating functions of the vasomotor nerves, and the action of curare on the voluntary muscles (in recent years this action has had application in anesthesia and electroconvulsive therapy).

Soon recognized as the leading experimental physiologist in France, Bernard received a number of awards and was appointed to prestigious positions, first at the Sorbonne (chair of general physiology), then the Academie des Sciences and the Collège de France (chair of experimental medicine). In time he produced a number of volumes, the most important of which remains the *Introduction à l'étude de la médecine expérimentale* (1865), preceded by the *Lectures on the Physiology and Pathology of the Nervous System* (1858). In these works he developed the concepts of "inner secretion," "inner environment," and "reciprocal inhibition," which were to become basic to the understanding of the functions of the organism. As a matter of fact, he always gave preeminence to function over form in his painstaking search for the essence of life. In later years he taught at the Museum of Natural History (1868) and was appointed senator of the empire (1869) and president of the Académie de France (1869). Of his many pupils, some became outstanding scientists in France, Germany, Russia, and the United States.

Stanley Hall received the first American doctorate in psychology from Harvard University. Hall was born in 1844 and raised on a farm in Ashfield, Mass. Endowed with great personal ambition, he attended Williams College, where he became enthusiastically inspired by philosophy and evolution. In 1867 he studied for the ministry at Union Theological Seminary in New York. He then spent some time learning theology and philosophy, as well as physiology and physics, in Bonn and Berlin. Back home in 1871, he took his degree in theology but soon resigned from his first pastorate. For three years he taught French and German languages and literature at Antioch College. His interest in psychology was spurred by reading Wundt's *Physiological Psychology*. Eventually he came under the influence of William James at Harvard, where in 1878 he presented his dissertation on the muscular perception of space. Following that he spent two years in Leipzig as Wundt's first American student.

Now definitely committed to the study of psychology, Hall embarked on an investigation of children's thoughts and beliefs through interviews and questionnaires. He slowly gained renown through a series of Saturday morning talks on education given at the invitation of the president of Harvard. In 1881 he accepted an offer to lecture at Johns Hopkins, and three years later he became full professor there. In 1883 he founded at Hopkins what is usually considered the first American psychology laboratory; a number of promising young men, such as Cattell and Dewey, were trained there. In 1887 he began to publish the *American Journal of Psychology*, the first journal of psychology in this country and still an important one today. Appointed the first president of the new Clark University in 1888, Hall aspired to develop a research center modeled on the style of the German universities. There he taught psychology and founded the *Pedagogical Summary* (now the *Journal of Genetic Psychology*) in 1891. The next year, with a few others, he founded the American Psychological Association, of which he was elected the first president.

The results of the many studies on children conducted by Hall and his associates were published in 1894 in *The Content of Children's Minds on Entering School*, a pioneering endeavor in the field of child psychology. It was followed by the monumental two-volume book *Adolescence* in 1904. By that time Hall was intrigued by the novelty of the psychoanalytic theories. In spite of the opposition of many of his colleagues and much of the public, he managed to invite Freud, Jung, and some other psychoanalysts for a series of conferences on the occasion of the 20th anniversary of Clark University in 1909. His longstanding interest in religion led him to publish the book *Jesus the Christ in the Light of Psychology* (1917), which was severely criticized by organized religion. He continued to work even after his retirement in 1920. In 1922 he published his two-volume book *Senescence*, the first work on geriatric psychology. Two of his books, *Recreation of a Psychologist* (1920) and *The*

Life and Confessions of a Psychologist (1923), are autobiographical. Hall died in 1924.

In retrospect, Hall's interests may appear rather fragmentary and scattered. However, he should be credited with two main accomplishments: he aroused interest in new fields, notably developmental psychology and psychoanalysis through his excellent skill as an organizer and publisher, and he maintained the evolutionary theory as the constant focus of his multifarious activity.

John B. Watson was born in Greenville, S.C. A rebellious and independent spirit from early years, at age 16 he entered Furman University, from which he obtained a master's degree in 1900. At that time he was already opposed to any religious influence. He then entered the University of Chicago, which was then dominated by George Mead and John Dewey. There he was particularly influenced toward experimental psychology by James R. Angell and toward a materialistic orientation of biological studies by Jacques Loeb, professor of physiology and originator of the theory of "tropism." Watson received his Ph.D. in 1903. In that same year he married a woman who belonged to a prominent family and continued to work at the University of Chicago as an instructor in experimental psychology and director of the psychological laboratory.

In 1913 Watson published his famous manifesto "Psychology as a Behaviorist Views It." In it he proclaimed that psychology "is a purely objective experimental branch of natural science. Its theoretical goal is the prediction and control of behavior." The following year he produced *Behavior: An Introduction to Comparative Psychology,* a defense of animal psychology and of the place that it occupies in the behavioral sciences. In this way Watson was advocating a new kind of psychology "in the third person," which was at variance with Wundt's psychology "in the first person" (the school of introspection) and Freud's psychology "in the second person" (based on the transference situation between the individual and the analyst).

The forceful and at times polemic way in which Watson presented his ideas had a great impact on the entire field of American psychology. Elected president of the American Psychological Association in 1915, he announced his support of the theory of conditional reflexes brought forward by the Russian neurologist V.M. Bekhterev. (Pavlov's main work on conditional reflexes did not become available in English until 1927.) The climate seemed ready for a shift in psychology from a speculative to a concrete orientation.

After a period of difficulties toward the end of World War I related to his criticism of a neurological test for pilots, Watson began the study of children at the Henry Phipps Clinic in Baltimore. He concluded that the emotional reactions of children can be reduced to three types: love, elicited by the gentle stimulation of the skin; rage, elicited by physical restraints; and fear, elicited by loud noises and loss of support. In 1919 he published his most famous book, *Psychology from the Standpoint of a Behaviorist.*

In 1920, at the peak of his career, Watson was divorced and soon afterward married Rosalie Rayner, his coworker at Hopkins. The reaction of the academic community was so strong that he was dismissed from his position and had to work as a salesman. He obviously revealed talent in this new occupation, for in three years he rose to the position of vice-president of a large advertising agency. He remained in the field of business until his retirement in 1946.

Watson's main interest, however, continued to be psychology, and he pursued it through lecturing (at Clark University and the New School for Social Research) and writing. His book *Behaviorism* (1925) contains the following famous statement: "Give me a dozen healthy infants, well-formed, and my own specific world to bring them up in and I will guarantee to take any one at random and train him to become any type of specialist I might select." As far as is known, this experiment was never carried out. In 1928, he produced *Psychological Care of the Infant and Child,* a popular book for the general public. It was followed the next year by *The Battle of Behaviorism,* a polemic against William McDougall, then professor at Harvard and the exponent of the doctrine of purposive behavior. Watson spent the last years of his life in Westport, Conn. He died in 1958.

Although Watson's theories were highly controversial, they were very stimulating for both his adherents and opponents. During his life neobehaviorism was flourishing, mainly through the work of C.L. Hull. After his death the spread of behavior therapy gave new meaning to Watson's work.

Kurt Goldstein was born in Kattowitz, Germany (now Poland). After obtaining a medical degree from the University of Breslau in 1903, he taught at the University of Königsberg (1907–1915) and then worked as director of the Institute for Research into the Aftereffects of Brain Injuries. He later became professor of neurology at the University of Frankfurt (1916–1929), followed by a short stay in Berlin (1929–1933). His firsthand experience with large numbers of brain-injured soldiers during World War I, coupled with the influence of the then-emerging movement of Gestalt theory, led him to consider the organism as a whole regardless of any particular deficit. Together with Wertheimer, Köhler, Koffka, and Gruhle, he was one of the cofounders of the Gestalt psychology journal *Psychologische Forschung* (1921–1938).

Forced by the Nazis to leave Germany, Goldstein emigrated to Amsterdam (1934–1935), where he wrote his classic volume *The Organism: A Holistic Approach to Biology Derived from Pathological Data in Man* (1934; translated into English in 1938). In it he presented the concept of the inborn potential toward self-realization as a driving force that puts the organism into action and achieves its optimal state when there is "adequacy" between the organism and the

world. Good gestalt is "a form of coming to terms of the organism with the world, that form in which the organism actualizes itself, according to its nature, in the best way." Poor gestalt, "the tendency to discharge any tension whatsoever is a characteristic expression of a defective organism, of disease." In fact, aphasic and brain-injured persons lack the ability to name objects as class symbols rather than experiencing the loss of words and word images, which indicates that while defects can be localized, functions cannot. In particular, Goldstein described the "catastrophic reaction" of brain-injured patients as a state of tremendous anxiety accompanied by a sense of "losing existence" or feeling unable "to be." By dividing human acts into the abstract and the concrete, he postulated that impairment in abstract thinking (attention, planning, discrimination, hypothesizing) leaves concrete operations unaffected, and vice versa. The Goldstein-Gelb and Goldstein-Scheerer tests were devised to measure the ability to form concepts and to diagnose brain lesions. Goldstein suggested that schizophrenics' behavior may be either concrete or abstract, but that it tends to become concrete in anxiety-arousing situations.

From 1936 to 1940 Goldstein was professor of psychiatry at Columbia University and chief of the Neurophysiological Laboratory at Montefiore Hospital in New York City. During the period 1938–1939 he delivered the William James lectures, which were published under the title *Human Nature in the Light of Psychopathology* (1940). He later served as professor of neurology at Tufts Medical School in Boston (1940–1945). From 1946 until his death in 1965 he taught at the College of the City of New York, Columbia University, and the New School for Social Research, and was guest professor at Brandeis University in Waltham, Mass. In 1962 he was one of the cofounders of the *Journal of Humanistic Psychology*. Among those particularly influenced by Goldstein were Abraham Maslow, the well-known promoter of "third force (humanistic) psychology," and Fritz Perls, who was the founder of Gestalt psychotherapy. Goldstein's *Selected Papers* were published posthumously in The Hague in 1971.

Am J Psychiatry 136:1, January 1979

SPECIAL SECTION: The Psychobiology of Depression—NIMH-Clinical Research Branch Collaborative Program

Introduction: Overview of the Clinical Studies Program

BY MARTIN M. KATZ, PH.D., AND GERALD L. KLERMAN, M.D.

THE IMPETUS for the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression stemmed from the growing concern with depression as a U.S. public health problem and the growing awareness that there had been some striking changes over the past 20 years in our conception of the nature and etiology of the affective disorders. New findings in the area of genetics and biochemistry inspired hypotheses implicating the chemistry of the endocrine and central nervous systems in ways quite different than had been thought in the past. There was reason to believe that we were on the verge of linking physiology, psychosocial factors, and behavior in these disorders, which would eventually make possible the development of a coherent and valid psychobiologic theory of depression. However, serious methodologic problems and the practical difficulties intrinsic to clinical research had seriously retarded progress toward this objective.

Because of these developments and the perceived obstacles, NIMH staff convened a conference in 1969 (1) to review progress and to consider ways of accelerating the pace of research in this sphere. The conferees were asked to analyze the state of the field and to develop a set of recommendations to guide future research. Their consensus regarding the major affective disorders was

1. That they are heterogeneous both in regard to their nature and their etiology.
2. That there is a subclass which is almost certainly hereditary in nature.
3. That a form of derangement of central nervous system chemistry is implicated in certain severe forms of the disorder.
4. That significant progress has been made in issues of diagnosis. There are now several systems of classification, e.g., the primary-secondary and bipolar-unipolar systems, which appear valid for different purposes; no one system, however, meets all of the requirements for research and for clinical practice.
5. That despite the advances in the conceptualization of nosologic systems, diagnostic practice remains sufficiently unreliable across clinical settings to make comparison of results of different studies consistently hazardous.
6. That the compelling hypotheses in the field which implicate genetics, biochemistry, and/or psychosocial factors in the etiology or nature of the depressive disorders derive from small studies and, thus, require replication.
7. That settings having a sufficient number and diversity of patients, adequate technical resources for conducting clinical and biological studies, and the willingness to conduct such replications would likely be rare, if they existed at all.

These observations, which span issues of nosology, clinical methodology, and the role of psychosocial factors, led to a broad set of recommendations on which this highly diverse group of basic scientists and clinical investigators again had reasonably high agreement.

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received May 4, 1978; accepted Sept. 15, 1978.

Drs. Katz and Klerman are Co-Chairmen, NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression. At the time this work was done, Dr. Katz was Chief, Clinical Research Branch, NIMH; he is now Research Professor, Department of Psychology, Long Island University, Brooklyn Center, University Plaza, Brooklyn, N.Y. 11201. Dr. Klerman is Administrator, Alcohol, Drug Abuse, and Mental Health Administration.

This work was done as part of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression: Clinical Studies and was completed with the cooperation and participation of the Collaborative Program investigators: Martin M. Katz, Ph.D., and Gerald L. Klerman, M.D., Co-Chairmen; Robert M.A. Hirschfeld, M.D., Coordinator; Martin B. Keller, M.D., Robert W. Shapiro, M.D., and James Barrett, M.D. (Boston); Jan A. Fawcett, M.D., and William A. Scheftner, M.D. (Chicago); George Winokur, M.D., and Nancy C. Andreasen, M.D. (Iowa City); Robert L. Spitzer, M.D., and Jean Endicott, Ph.D. (New York); and Eli Robins, M.D., Paula J. Clayton, M.D., Theodore Reich, M.D., Amos Welner, M.D., and Jack Croghan, M.D. (St. Louis).

RECOMMENDATIONS OF NIMH CONFERENCE

First, it was clear that the technical obstacles noted would significantly interfere with the capacity to generalize results from one study to another; more importantly, they would prevent certain kinds of research from actually getting done. The foremost technical problem was establishing consensus on and reliability of the measurement of the critical symptomatic and behavioral facets of the various subtypes of affective disorder. An interview method that would be sufficiently comprehensive and would be capable of reliable application across different clinical settings would have to be developed or adapted from prior instruments.

Second, there was need to resolve more basic nosologic issues and to clarify the relative values of the various systems of classification currently in practice in the field. Because new nosologic systems have arisen (based, for example, on genetic findings) that should, for purposes of research, replace earlier systems, it was necessary to determine the reliability with which they can be applied and to compare the new with the traditional systems vis-à-vis their relative validities for research and practice. The second recommendation, then, was to initiate research aimed directly at resolving the issues underlying the uncertainty of nosology in this field.

Third, aware of the powerful influence that the new genetic findings and biochemical theories had already had on the course of research in the entire field, the group saw a need to develop the means or capacity to conduct studies aimed at confirming or disconfirming critical findings arising from research in these areas.

Certain research objectives could not possibly be met without a situation in which a large number of patients of certain types were available. Research of a multisystem nature (i.e., simultaneous investigation of central nervous system, endocrine, and behavioral functioning) requires an array of patients, a range of technology, and an unusual combination of expertise—requirements that are not likely to be found in any one setting. Because of the multifaceted nature of this class of clinical conditions, research on its nature or etiology requires a somewhat unique strategy. It became clear that settings in which all of the clinical resources, i.e., expert clinicians, adequate samples of relevant patient groups, and such technical resources as biological and clinical scientists, were virtually nonexistent. It was also necessary that the interests and capacities to develop clinical methodology and to conduct replicative studies in the biological sphere be available.

What evolved from these discussions was the clear need to develop mechanisms of collaboration across disciplines, laboratories, and clinical settings that would maximize the capacity of the program and expedite the solution of these problems. In developing such a mechanism, it was important that it be designed to complement and to stimulate, not to stem or in any sense replace the efforts of independent laboratories, in moving forward on basic problems in this area.

The collaborative mechanism would, therefore, focus on methodologic problems currently not being studied, on the need for replication, and on conducting research that independent laboratories were not currently capable of carrying out.

With this set of recommendations as background, the Clinical Research Branch of the National Institute of Mental Health convened an advisory group on collaborative research on the psychobiology of the affective disorders. This initial group, formed in 1971, eventually divided into a biological studies group and a clinical studies group. The biological studies group concentrated on the development of replicative research to test hypotheses implicating CNS and endocrine chemistry and their links with behavior in depression. Through the collaboration of five investigative groups and NIMH staff, that research is currently in operation. Its rationale and design are described elsewhere (2).

THE CLINICAL STUDIES PROGRAM

The clinical studies group is comprised of centers at Massachusetts General Hospital and Harvard Medical School, Boston; Rush-Presbyterian-St. Luke's Medical Center, Chicago; the University of Iowa, Iowa City; the New York State Psychiatric Institute, New York; the Washington University School of Medicine, St. Louis; and NIMH, Rockville, Md. Through the years it has focused its efforts on

1. The development of assessment methodology to be applied to a wide range of clinical problems, primarily in defining the basic dimensions of psychopathology and the relevant clinical phenomena for the diagnosis of depression.
2. The design of research to test the relative validity of various extant nosologic systems in research and in clinical practice.
3. The development of studies to replicate findings and to test new hypotheses about genetic transmission.
4. The testing of hypotheses about the role of personality and environmental factors in influencing the course and nature of the depressive episode.

During the past 5 years of collaborative effort, the group has developed the conceptual bases for and designed research aimed at these objectives. The objectives of the current program are described in appendix 1. This group has also constructed assessment methods of major significance for research on diagnosis, e.g., the Schedule for Affective Disorders and Schizophrenia (SADS) (3) and the Research Diagnostic Criteria (RDC) (4), which are already widely used in the field and in clinical practice.

Having completed the groundwork, the group then initiated, with National Institute of Mental Health support, a major pilot effort across four of the centers to

refine and extend the method development and to assess the feasibility of a full-scale intercenter investigation to conduct collaborative research on nosologic, genetic, and psychosocial issues. That pilot study lasted 2 years and was successful from the standpoint of what it was able to accomplish across the four centers and what it indicated was not possible to accomplish at this time.

CONCLUSION

To communicate in broad outline the nature of the program, the emphasis in the set of articles presented here is more on description than on actual results. The articles include broad descriptions of the diagnostic methodology (the SADS and RDC), applications of their use, some preliminary work on the application of techniques for studying personality, and, in the examination of the varied meanings of the diagnosis of neurotic depression, an example of how the program proper will be applied to resolve current issues of controversy that cut across nosologic systems.

The major strength of the overall effort will in the long run lie in its capacity to stimulate and extend independent basic research on depression. We expect to contribute to this goal by providing the clinical methodology, by differentiating through replicative studies the hard from the soft findings, and by using the collaborative mechanism to conduct research that is not possible in one laboratory or clinical setting.

The depressions, like all severe mental disorders, are conditions of the whole organism; their etiologies are not likely to be determined by any one scientific discipline. Research involving the collaboration of disciplines and settings is essential in this field and complements our attempts through research in independent laboratories to progress more rapidly in resolving these critical public health issues. Although preliminary, we trust that these reports will serve as a stimulus and provide the base for the more definitive work to be carried out through this unusual collaborative effort over the next 5 years.

APPENDIX 1
Objectives of the Clinical Studies Group of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression

I. Clinical psychopathology
  A. Comparative nosology
    1. Assess strengths and weaknesses of various classification systems
    2. Assess predictive validity
  B. Phenomenology
    1. Interrelate observations from clinical judgment, community behavior, and self-report
    2. Identify dimensions of depression
    3. Determine if there is a natural typology of depression
  C. Psychosocial factors
    1. Interrelationships of psychosocial stresses, social support systems, personality, and sociodemographic qualities
II. Genetics/family
  A. Family
    1. Correlate familial psychopathologic rates with nosology class of proband
  B. Genetics
    1. Determine specific mode of transmission through linkage and extended pedigree analysis (or studies)

Use of the Research Diagnostic Criteria and the Schedule for Affective Disorders and Schizophrenia to Study Affective Disorders

BY JEAN ENDICOTT, PH.D., AND ROBERT L. SPITZER, M.D.

In a pilot study of 150 manic or depressive patients, the authors used the Research Diagnostic Criteria (RDC) and the Schedule for Affective Disorders and Schizophrenia (SADS) to perform preliminary analyses of symptom pictures of the index episode of different diagnostic groups, joint diagnostic classification of the different subtypes of major depressive disorder, and differential outcome by diagnostic groups. The results suggest that schizophrenic symptoms in affective disorders do have diagnostic and prognostic significance, that the term "psychotic depression" should be limited to impaired reality testing without reference to degree of incapacitation, that situational-nonsituational and endogenous-nonendogenous classifications are separate depressive subtypes, and that it may not be true that patients with endogenous major depressive disorder have a better prognosis than patients with nonendogenous depression.

TWO PROBLEMS have plagued investigators in the study of affective disorders. The first and most important problem has been the absence of agreed upon sets of criteria that would enable investigators to compare the results of studies which use different ways of classifying patients. As a result, it is usually impossible to know if one investigator's patients who are characterized, for example, as having "severe endogenous depression," correspond to another investigator's patients described as having "psychotic depression." The second problem has been the absence of uniform procedures for collecting the information used to make diagnoses and to describe the characteristics of the study samples.

As part of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression, two new procedures were developed to minimize these problems: the Research Diagnostic Criteria (RDC) (1) and the Schedule for Affective Disorders and Schizophrenia (SADS) (2). This article focuses on the use of the RDC and the SADS in a pilot study that was part of the Collaborative Program and presents preliminary data on the use of these procedures for the study of affective disorders.

DESCRIPTION OF RDC AND SADS

The Research Diagnostic Criteria (RDC) provide sets of specific inclusion and exclusion criteria for a large number of functional psychiatric disorders, with particular emphasis on various ways of subtyping affective disorders. A single subject can be categorized in a variety of non-mutually exclusive ways, such as by the presence or absence of endogenous phenomenology, situational stresses, psychotic features, etc. We have described elsewhere (3) the rationale behind the selection of the RDC categories and criteria as well as initial interjudge reliability studies. The reliabilities obtained for the RDC categories are far above those generally obtained for clinical diagnosis in either joint interviews or test-retest interviews. Whereas most studies of diagnostic reliability yield kappas (an index of reliability that corrects for chance agreement) that range from .4 to .6 (4), the kappas for the RDC were usually above .7 and frequently above .8.

The Schedule for Affective Disorders and Schizophrenia (SADS) was developed in conjunction with the RDC in an effort to reduce information variance in both the descriptive and diagnostic evaluation of a

subject. The SADS is an interview schedule that interviewers use to ensure adequate coverage of critical areas of psychopathology and functioning.

Part I of the SADS is unique among rating scale procedures in that the items are used to describe the features of the current episode of illness when they were at their most severe, in contrast to most psychiatric rating scales, which cover a set time period regardless of the relationship of the time of the evaluation to the beginning and peak of the episode. In addition to the collection of data relevant to an evaluation of the diagnosis, prognosis, and phenomenology of a current episode of illness, part I of the SADS is also designed to measure change. Many of the scaled items are also judged for the level of severity during the week preceding the evaluation. This subset of items can then be used for subsequent evaluations to measure change using the Change version of the SADS (SADS-C). Part II of the SADS focuses primarily on past history, although some items describe current behaviors, and contains items relevant to prognosis and overall severity of illness as well as diagnosis. The rater should be able to make an RDC diagnosis at the end of the SADS evaluation.

The rationale and description of the development of the SADS and an initial summary scoring system, as well as the results of the reliability studies of the Collaborative Program, are described elsewhere (5). The reliabilities for the individual items and for five composite summary scales were found to be very high under both joint and test-retest conditions, with most reliability coefficients (intraclass R) .75 or higher.

PILOT STUDY

The RDC and SADS were used in a pilot study designed to assess the feasibility of the procedures, to determine their reliability, and to perform preliminary analyses regarding symptom pictures of the index episode of different diagnostic groups, joint diagnostic classification of the different subtypes of major depressive disorder, and differential outcome by diagnostic groups. The subjects were 150 newly admitted inpatients who had either a manic or depressive syndrome and met other screening requirements for entry into the study; all of the subjects gave informed consent. The data were collected by four of the centers participating in the Collaborative Program.

Ninety of the 150 patients had an RDC diagnosis of major depressive disorder for the index episode, and 9 were diagnosed as having schizo-affective disorder, depressed subtype. We focus here on subgroups of these 99 patients. As defined in the RDC, a diagnosis of major depressive disorder requires an episode of illness of at least one week's duration, in which there is a prominent and relatively persistent dysphoric mood or pervasive loss of interest or pleasure, accompanied by at least 4 of 8 specific features of the depressive syndrome. In addition, certain features that suggest schizophrenia must be absent. In contrast, the diagnosis of a schizo-affective disorder, depressed subtype, requires the presence of the positive features of the major depressive disorder as well as at least 1 of the symptoms suggesting schizophrenia.

CONTRASTS BETWEEN SCHIZO-AFFECTIVE DISORDER AND PSYCHOTIC MAJOR DEPRESSIVE DISORDER

There is no consensus as to how to define schizo-affective disorder or whether it should be defined as a separate group (6–10). Schizo-affective disorder, depressive subtype, is defined in the RDC as an illness in which there is a temporal overlap of both a major depressive syndrome and specified schizophrenic-like features. Psychotic major depressive disorder was defined as a major depressive syndrome with delusions or hallucinations or depressive stupor.[1] We tested two hypotheses regarding the characteristics of the index episode: 1) The onset of schizo-affective disorder is more often associated with stress and is more rapid than that of psychotic major depressive disorder, and 2) schizo-affective disorder is associated with more signs of disorganization, and the delusions associated with it are more numerous and of greater variety than with psychotic major depressive disorder.

Table 1 indicates which of the 120 scaled items in the SADS were significantly different for patients having schizo-affective disorder, depressive subtype (N=9) and those having psychotic depression (N=22). Items involved in the differentiating criteria are noted at the bottom of the table and, as expected, are significantly different. In contrast to the hypothesis, there were no differences on the two items evaluating stress (the rater's judgment and the patient's judgment). However, as hypothesized, the duration of the onset was significantly longer in the patients with psychotic major depression (one to two months versus one to two weeks). A higher percentage of patients in the schizo-affective group were found to be delusional (100% versus 54%), although the mean score was significantly higher only on the persecutory subtypes. The overall severity of delusions was also greater in the schizo-affective group, as was that of hallucinations and the global measurement of symptoms and impairment, the GAS score. The depressive syndrome of the psychotic major depressive patients was also characterized by more endogenous features than was that of the schizo-affective patients.

Although the RDC criteria differentiating the two groups of patients had little prior research support, the prior history and follow-up data of the pilot study suggest that the criteria used have some validity beyond that which is merely definitional. The schizo-affective patients had had more previous episodes and more residual impairment after previous episodes than the pa-

[1]The criterion of depressive stupor is no longer used.

TABLE 1
Mean Scores[a] on the SADS Part I Items That Differed Significantly for Patients with Schizo-Affective Disorder, Depressed Type and Patients with Psychotic Major Depressive Disorder[b]

Item	Schizo-Affective Disorder, Depressed Type (N=9)	Psychotic Major Depressive Disorder (N=22)	t[c]	ϵ
Not differentiating criterion				
Duration of episode	3.88	5.25[d]	2.36	.42
Duration of onset	3.57	5.20[d]	2.42	.45

tients with psychotic major depression, and on follow-up two years later they were found to have more depressive symptoms and role impairment. Fifty-five percent of the schizo-affective group and 18% of the psychotic major depressive patients were found to be out of work because of psychopathology. Similarly, only 33% of the schizo-affective patients were found to have a GAS score above 60 whereas 50% of the psychotic major depressive patients had such scores.

The sample sizes in this study are small and there is obviously a need for replication. However, these findings do suggest that it may be premature to conclude, as have Pope and Lipinski (10), that "schizophrenic" symptoms occurring in the course of an affective disorder have no diagnostic or prognostic significance. Our findings are consistent with those of Croughan and associates (9), who also found that the presence of certain psychotic features in an affective illness was associated with a more chronic course, although their definition of schizo-affective disorders differs somewhat from that used in the RDC.

Contrasting Definitions of Psychotic Depression

Two of the criteria that have been used in defining psychotic depression are impaired reality testing and degree of incapacitation. These two criteria are split in the RDC into psychotic (having to do with reality testing) and incapacitating (having to do with functional impairment). A cross tabulation of these two subtypes revealed that 74% of the psychotic patients were incapacitated but only 40% of the patients with a diagnosis of incapacitating were also psychotic. Furthermore, the two groups differed in such important behavioral correlates as psychomotor retardation. Whereas only 48% of the patients with impaired reality testing had significant retardation, 70% of those who were functionally incapacitated were so described.

These findings indicate what most clinicians have long known: the broad definition of the term psychotic that was given official sanction in *DSM-II* (7) combines two very different concepts: impairment in reality testing and impairment in ability to function. Descriptively, it would seem to make better sense to restrict the use of the term psychotic to impaired reality testing, as done in the RDC and in the draft of *DSM-III* (11).

RELATIONSHIP BETWEEN ENDOGENOUS-NONENDOGENOUS AND SITUATIONAL-NONSITUATIONAL MAJOR DEPRESSIVE DISORDERS

The absence of stress and the presence of endogenous features are frequently used, in a confusing and inconsistent fashion, to define endogenous depressions. The RDC subtypes of major depressive disorder use both concepts. A situational major depressive disorder is defined in the RDC as a depression that is judged to have developed after an event or in a situation that seems likely to have contributed to the appearance of the episode at that time. An endogenous major depressive disorder is defined in the RDC on the basis of phenomenology of the current episode. There must be several of the clinical features that are repeatedly reported in the literature as characterizing depressive illnesses which arise in the absence of life events and which seem particularly responsive to somatic therapy, e.g., terminal insomnia, weight loss, and lack of reactivity of mood.

The two categories allow classification by both ways of subtyping as well as by a comparison of the features associated with the defining characteristics. Diagnoses of 45 of the 90 patients with major depressive disorder were subclassified as situational and 52 were called endogenous subtype. The cross tabulation of the subtypes indicates that 42% of the situational patients were also diagnosed as having endogenous subtype; 73% of the nonsituational patients were also called endogenous. Reversing the procedure revealed that 37% of the endogenous patients were called situational and 68% of the nonendogenous patients were called situational.

The cross tabulation data as well as those shown in tables 2 and 3 indicate that although there is considerable overlap in the characteristics of patients classi-

fied by the two sets of criteria, the results differ depending on the definition used. For example, there was no difference in the overall assessment of the severity of illness (Global Assessment Scale rating) and only one significant difference in the summary scale scores between the situational and the nonsituational subgroups, although one might expect that situational depressions (often called "neurotic depressions") would show less severe impairment. In contrast, the patients classified as endogenous were significantly more impaired than were those classified as nonendogenous, as would be expected. These findings support the separate use of these two clinical features in subtyping depressive episodes and are in keeping with Klein's focus (12) on phenomenology and suggested name change from endogenous to endogenomorphic depression.

Prognostic Implications of Endogenous Features

Another hypothesis we tested in a preliminary fashion was that patients with endogenous major depressive disorder will have a good prognosis in that they will have less symptomatology subsequent to episodes of illness than will patients with nonendogenous major depressive disorder. Two-year follow-up data on 33 patients with an index episode of endogenous major depressive disorder and 21 patients with an index episode of nonendogenous major depressive disorder did not confirm this hypothesis. If anything, the trends are in the opposite direction; more of the nonendogenous patients had GAS scores above 60 (indicating minimal or no symptomatology or impairment in functioning) than did the endogenous patients (81% versus 72%). Furthermore, 39% of the endogenous patients were unable to work at the time of follow-up because of psychopathology, whereas only 24% of the nonendogenous patients were so impaired.

Again, although the sample sizes are small, these findings call into question a clinical assumption frequently repeated in the literature regarding the prognostic significance of endogenous features.

CONCLUSIONS

The studies reported here demonstrate that the conjoint use of two newly developed procedures, the Research Diagnostic Criteria (RDC) and the Schedule for Affective Disorders and Schizophrenia (SADS), have considerable potential for the testing of various hypotheses regarding the classification of affective disorders. Although the sample sizes are small, the data from this pilot study of the Collaborative Program on the Psychobiology of Depression raise questions about widely held assumptions regarding cross-sectional symptomatology, course, and the relationship between subtypes of affective disorders.

Neurotic Depressions: A Systematic Analysis of Multiple Criteria and Meanings

BY GERALD L. KLERMAN, M.D., JEAN ENDICOTT, PH.D., ROBERT SPITZER, M.D., AND ROBERT M.A. HIRSCHFELD, M.D.

Neurotic depression, the most commonly used psychiatric diagnosis, has multiple meanings that are often used interchangeably in clinical practice. The authors identify six different meanings of neurotic depression and present data from a study of 90 depressed inpatients to determine how many patients met several different criteria; 16 patients met four sets of criteria. The overlap that exists between the different meanings is higher than chance alone but not sufficiently high to allow complete interchangeability. Until new diagnostic classes are developed, the authors recommend that the term "neurotic depression" no longer be used clinically because of its vagueness.

AMONG THE AFFECTIVE disorders the nosologic status of "neurotic depressions" remains uncertain and controversial. Whereas considerable progress has been made in the past two decades in clarifying the status of other affective disorders, especially manic-depressive illness, neurotic depression remains a diagnosis of theoretical unclarity and clinical confusion. For manic-depressive illness the range of symptoms has been well described, and two main clinical forms have been distinguished—unipolar and bipolar. The validity and utility of the unipolar-bipolar distinction has been demonstrated by correlations with familial and genetic patterns, with response to treatment (especially to lithium and the tricyclic antidepessants) and biochemical and psychophysiological processes, and with clinical course and outcomes (1). However, manic-depressive illness occurs in only about 10%–15% of patients with affective disorders. Comparable data are not available for the neurotic depressions, and the absence of such information contributes to confusion in theory, research, and clinical practice.

Depressive neurosis (*DSM-II* code 300.4) is a very frequent clinical diagnosis, probably the most common diagnosis made among the affective disorders (2) (NIMH Biometric Division Report, 1975). In addition to its high treatment rate, the epidemiologic evidence from community surveys indicates a high prevalence of untreated cases in adult populations, especially among women (3). Another consistent finding from epidemiologic studies is that the neurotic forms of depression are far more common than manic-depressive illness or other psychotic forms of depression (4).

Even with the clinical frequency of diagnosis and the epidemiological evidence for high prevalence of depressive neurosis, there continues to be a lack of clarity and precision as to the range of phenomena to be subsumed by the nosologic class and vagueness as to the criteria for the diagnosis. This contributes to a relatively low reliability of diagnostic agreement among clinicians—in clinical settings if not in research efforts. Spitzer and Wilson (5), in reviewing diagnostic agreement among various clinical conditions; found the interrater reliability coefficients for neurotic depression to be .37, far lower than those achieved for mental deficiency, organic brain syndromes, or schizophrenic psychoses, all of which ranged above .5.

Disagreement exists about not only the diagnostic criteria but also the specificity of treatment. Those clinicians who presume that neurotic depressions have a psychosocial or psychodynamic etiology consider psychotherapy the treatment of choice (6, 7). Other observers, alleging that neurotic states including depression have high rates of spontaneous remission, question the necessity, desirability, or social value of psychotherapeutic intervention (8).

Comparable disagreement exists about the role of

Dr. Endicott is Associate Professor of Clinical Psychology, Department of Psychiatry, Columbia University College of Physicians and Surgeons, where Dr. Spitzer is Professor of Clinical Psychiatry; Dr. Endicott is also Deputy Director, Biometrics Research, New York State Psychiatric Institute, New York, N.Y., where Dr. Spitzer is Chief, Psychiatric Research (Biometrics Research). Dr. Hirschfeld is Chief, Depression Section, Clinical Research Branch, National Institute of Mental Health, and Coordinator, National Institute of Mental Health-Clinical Research Branch Collaborative Program on the Psychobiology of Depression.

This work was done as part of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression: Clinical Studies and was completed with the cooperation and participation of the Collaborative Program investigators: Martin M. Katz, Ph.D., and Gerald L. Klerman, M.D., Co-Chairmen; Robert M.A. Hirschfeld, M.D., Coordinator; Martin B. Keller, M.D., Robert W. Shapiro, M.D., and James Barrett, M.D. (Boston); Jan A. Fawcett, M.D., and William A. Scheftner, M.D. (Chicago); George Winokur, M.D., and Nancy C. Andreasen, M.D. (Iowa City); Robert L. Spitzer, M.D., and Jean Endicott, Ph.D. (New York); and Eli Robins, M.D., Paula J. Clayton, M.D., Theodore Reich, M.D., Amos Welner, M.D., and Jack Croghan, M.D. (St. Louis).

drug treatment. Recommendations regarding the value of drug treatment for neurotic depressions tend to follow the clinicians' and investigators' conceptions of the nature of the disorder. Those clinicians favoring psychogenic causation tend to be cautious, if not negative, toward the use of drugs. When drugs are prescribed by them, diazepoxide derivatives and other antianxiety drugs are used. In contrast, clinicians who regard neurotic depressions as mild forms of affective disorders are more prone to use drug treatment and to prescribe the tricyclic antidepressants or the MAO inhibitors (9). Although early research studies on antidepressant drugs and many Food and Drug Administration package inserts for tricyclics assert the specific value of tricyclic antidepressants for psychotic forms of depression, clinical experience and recent research trials increasingly support the value of tricyclics for neurotic depressions, and there has been a resurgence of interest in MAO inhibitors in atypical neurotic depressions—those with mixed anxiety or phobic features.

DEFINITIONS OF CRITERIA FOR NEUROTIC DEPRESSION

Reviewing these divergencies in diagnostic practice and treatment recommendations has led us to identify a number of different meanings for neurotic depression:

1. *Neurotic depressions are less socially incapacitating.* This usage is synonymous with a judgment of mild severity of social dysfunction. These depressions allow the individual to continue his or her social functioning, although there may be personal distress and inner misery.

2. *Neurotic depressions are nonpsychotic.* In this usage, neurotic depression is a residual category for those patients not showing psychotic features and is contrasted with a psychotic depression; the patient is considered to have a neurotic depression if there is an absence of hallucinations, delusions, confusion, memory impairment, or other signs of impairment of reality testing and intactness of higher mental functions.

3. *Neurotic depressions do not present endogenous symptoms.* This usage defines a clinical picture without "endogenous" symptoms, i.e., early morning wakening, weight loss, retardation, guilt. Some observers have asserted that in neurotic depression there is not only the absence of the endogenous symptom pattern but also the presence of a characteristic constellation of symptoms of its own, with self-pity, irritability, reactivity, and fluctuating symptoms (labeled the self-pitying constellation) (10).

4. *Neurotic depressions follow a stressful event that is usually, but not exclusively, psychosocial in nature.* This usage is synonymous with "situational depression" or "reactive depression." It is presumed that the stressor is the immediate proximate or contributing cause and has temporarily overwhelmed the previously normal individual's capacity to cope and adapt. Such depressions are seen as extensions of normal states, quantitatively rather than qualitatively different from the normal reactions of loss, separation, disappointment, and other precipitants of a normal mood shift.

5. *Neurotic depressions are the consequences of a long-standing maladaptive personality pattern.* These depressions represent merely the latest "ripple" on a long-standing wave of personality inadequacies and social maladaptations. This type of depression is sometimes called "characterological depression" (11) or "depressive personality." This concept emphasizes predisposition, in terms of long-standing preexisting personality structure and character pathology of the patient.

6. *Neurotic depressions are the result of unconscious conflicts, according to psychoanalytic theory.* These depressions depend on four basic factors: 1) mood changes following interpersonal loss, disappointment, or deprivation; 2) a fall in self-esteem; 3) conflicts over the aggressive drive; and 4) a premorbid personality structure involving narcissism, dependency, and ambivalence (6).

Because of these multiple alternative criteria, some investigators and clinicians have recommended discarding the diagnostic term (12). For example, the criteria developed by the Washington University group in St. Louis do not include neurotic depression (13). Furthermore, draft versions of *DSM-III* have eliminated "neurotic depression" and have instead classified such cases as "major depressive disorder," "chronic depressive disorder," "atypical depressive disorder," or "adjustment disorder with depressed mood."

Patients may receive a diagnosis of neurotic depression on the basis of any or all of these criteria. The implications as to etiology, clinical course, response to treatment, family history, psychosocial aspects, and other relevant variables of using one criterion set rather than another are unknown. In fact, even the approximate likelihood of meeting one criterion given that another has been met is unknown. For example, if a depression is nonpsychotic will it necessarily also be reactive? This paper addresses some of these issues. Specifically, a group of depressed patients was carefully diagnosed according to the Research Diagnostic Criteria (RDC) (14). The degree of overlap among the various neurotic depression groups was assessed and personality, symptomatic, social behavior, and other characteristics of the group were examined. It should be noted that the study focused on only the first four criteria and did not include assessments of long-standing maladaptive personality patterns.

METHOD

The data reported here derive from the pilot study conducted by the Clinical Studies group of the NIMH-

Clinical Research Branch Collaborative Program on the Psychobiology of Depression. The research groups at the four participating centers used a common protocol.

At the four centers consecutive admissions to the adult inpatient units were screened for depression and mania by a research assistant on the basis of a verbal report of mood, behavior, and associated symptoms. They were then evaluated with the Schedule for Affective Disorders and Schizophrenia (SADS) (15) and were diagnosed with the Research Diagnostic Criteria (14). Those patients who received a diagnosis of major depressive disorder were further diagnosed into the following nonmutually exclusive subcategories (as well as several others):

1. Psychotic major depressive disorder—must contain delusions, hallucinations, or depressive stupor (mute and unresponsive).

2. Incapacitating major depressive disorder—either A or B is required.

Group A. Because of severity of symptoms, the patient is *unable to function* at work or at school, or take care of the house for at least one week (or if hospitalized was so *impaired* that *obviously* could not work). (Do not count mere refusal to do tasks.)

Group B. Because of severity of symptoms, the patient is *unable* to feed or clothe himself or maintain minimal personal hygiene without assistance.

3. Endogenous major depressive disorder—from groups A and B a total of at least four symptoms for probable, six for definite, including at least one symptom from group A.

Group A. 1) Distinct quality to depressed mood, i.e., depressed mood is perceived as distinctly different from the kind of feeling the patient would have or has had following the death of a loved one; 2) lack of reactivity to environmental changes (once depressed, the patient does not feel better, even temporarily, when something good happens); 3) mood is regularly worse in the morning; 4) pervasive loss of interest or pleasure.

Group B. 1) Feelings of self-doubt or reproach or excessive or inappropriate guilt; 2) early morning awakening or middle of night insomnia; 3) psychomotor retardation or agitation (more than a mere subjective feeling of being slowed down or restless); 4) poor appetite; 5) weight loss (two pounds a week over several weeks or 20 pounds in a year when not dieting); 6) loss of interest or pleasure (may or may not be pervasive) in usual activities or decreased sexual drive.

4. Situational major depressive disorder—illness has developed after an event or in a situation that seems likely to have contributed to the appearance of the episode at that time. In making this judgment consider the amount of stress inherent in the event or situation, the cumulative effect of such stresses, and the closeness of the events to the onset or exacerbation of the depressive episode.

RESULTS

Sample Characteristics

A total of 150 patients (98 women and 52 men) were selected from the four participating hospitals. The median age was 33 years. The sample was predominantly white (82%). By religious background, 22% of the sample was Protestant, 45% was Catholic, 6% was Jewish, and 27% was unaffiliated. Two-thirds of the sample had been married, and one-third was single. Of those who had been married, however, a substantial percentage (27%) of the total sample was divorced or widowed. The sample was relatively well educated, 50% having had more than a high school education.

Of the 150 patients, the data analysis will focus on the 90 who had major depressive disorder. The remaining were schizo-affective, had a manic episode, or had a depressive syndrome not meeting the criteria for major depressive disorder.

Of the 90 patients with major depressive disorder, multiple noninclusive diagnostic assessments were made according to the RDC criteria on a number of different subtypes of current psychiatric interest (see table 1). Diagnoses were made independently by each of two clinicians on the basis of an interview conducted by one and silently observed by the other. Interrater reliabilities were very high (kappa=0.80) (14).

Relationship Among Alternative Diagnoses

Of the 90 patients with major depressive disorder, 42%, 53%, and 50% did not meet the criteria for endogenous major depressive disorder, psychotic major depressive disorder, or incapacitating major depressive disorder, respectively. Fifty percent were diagnosed as meeting the criteria for situational major depressive disorder.

The results clearly indicate that the alternative diagnostic criteria for neurotic depression yield different, although overlapping, groups of patients. This may seem a trivial finding; however, many clinicians and researchers use this term to refer to any or all of the groups and presume that they are identical.

Of the 38 patients who did not evidence endogenous clinical features, 79% were nonpsychotic, 66% were not socially incapacitated, and 68% had a clear precipitant. In parallel, of those patients who did not have psychotic symptomatology (N=67), less than half (45%) were nonendogenous, about two-thirds (63%) were not socially incapacitated, and about half (54%) had a precipitant. Of the nonincapacitated depressive patients (N=48), 52% were also nonendogenous, 88% were, not surprisingly, nonpsychotic, and 58% had a precipitant. Finally, of the 45 situational depressives, 58% were nonendogenous, 80% were nonpsychotic, and 62% were nonincapacitating.

Overall, the degree of overlap between any two groupings ranged between half and two-thirds, with the exception that it was rare for a psychotic depressive to be found among the other three groupings.

Conversely, among the 52 patients with endogenous

TABLE 1
Subtypes of Major Depressive Disorder (N=90) for the Present Illness*

Endogenous	52	58
Agitated	17	19
Retarded	23	26
Situational	45	50
Simple	57	63

*Diagnoses were counted as present if they were rated probable or definite.

symptoms, 37% were also diagnosed as having a situational precipitant. This goes against one of the major classical criteria for endogenous depression, which holds that the depression comes on in the absence of a situational life stress. Of the 90 patients with major depressive disorders, only 18% (N=16) met all four criteria for neurotic depression.

DISCUSSION

The findings confirm that the various criteria for neurotic depression are not interchangeable. Some degree of overlap of patient groups does exist; this degree is greater than would be expected by chance alone, but it is not sufficiently strong to allow complete interchangeability.

It is important to underscore that the lack of agreement among the various definitions of neurotic depression is not due to observer variance. As previously noted, the interjudge symptomalogic and diagnostic reliabilities were very high. This was due in large part to the use of a semi-structured clinical interview, explicit diagnostic criteria, and training programs. The degree of agreement is far above that reported by Spitzer and Wilson in their review of previously published literature on neurotic depression (5). This confirms the expectation that when explicit criteria are used, the meanings of neurotic depression are specified, and the clinical interviewers are trained, the agreement rises substantially into acceptable levels. Thus, the lack of agreement simply reflects the fact that these various criteria define different groups.

Several prior investigators have developed affective nosologies based on clusters of cross-sectional symptoms. Overall (16), for example, has proposed three depressive types. Two of the three types (namely, anxious and hostile) might be regarded as variants of neurotic depression. Paykel (17), using a cluster analysis technique, devised a four-fold typology, three of which might also be regarded as neurotic (nonpsychotic). Derogatis (18), using factor analysis, derived three types of neurotic affective disorder to include patients with a mixture of anxiety and depression. The Derogatis typology is based on data from patient self-reports, the Hopkins Symptom Checklist.

After a number of alternative diagnostic groups subsumed under the rubric of "neurotic depression" have been identified, these groups can be compared as to symptom profile, family background, follow-up study, or personality profiles. These diagnostic schemes, in addition to the one described in this paper, were developed on the basis of symptomatology and, to some extent, psychiatric history. With the exception of the Overall system, for which there were some differential drug response data reported, there are no validation data such as clinical course, follow-up, familial psychopathology, or personality data. Such research is now underway as part of the clinical studies of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression.

Our objection to the term neurotic depression involves theoretical as well as empirical criticisms. It has tended to carry with it various etiological assumptions. For the most part, clinicians have regarded neurotic depression as having nonorganic (i.e., psychosocial, environmental) causes. However, there has been divergence as to whether these causes are to be found in acute situational stress, precipitating situational reactions, or long-standing maladaptive personality features. The results provided here, in addition to studies already cited in the literature, lead to the conclusion that these alternative meanings, while they share a common view as to the psychosocial environmental origin of neurotic depression, are sufficiently diverse as not to be interchangeable or identical. Therefore, we recommend that in the search for etiological bases for alternative meanings to neurotic depression, relatively homogeneous groupings are required to test hypotheses about the antecedent causal relationship of the symptom pattern to postulated causes such as life stress, personality, or social change.

CONCLUSIONS

A test of the interrelationship of four of the different meanings (nonpsychotic, nonendogenous, nonincapacitating, situational) indicates only a modest degree of overlap. We therefore conclude that the value of using the term neurotic depression is limited.

The results of this study have influenced and supported the decision of the American Psychiatric Association's Task Force on Nomenclature and Statistics to drop the category of neurotic depression and instead to enable the clinician to characterize depressive disorders along the following dimensions, using a multiaxial approach: 1) course (episodic versus chronic) (Axis I); 2) presence or absence of bipolarity (Axis I); 3) severity (including psychotic or not) (Axis I); 4) personality pattern or disorder (Axis II); 5) presence of life stress (Axis IV); 6) highest level of adaptive functioning in the past year (Axis V).

This approach should enhance precise communication among clinicians and researchers and allow more

precise determinations of the relationship of subtypes of the heterogeneous group of disorders previously called neurotic depression to treatment outcome, genetics, and influence by life stress or other psychological factors.

Secondary Depression: Familial, Clinical, and Research Perspectives

BY NANCY C. ANDREASEN, M.D., AND GEORGE WINOKUR, M.D.

The authors evaluate the clinical and research significance of the diagnosis of secondary depression by comparing 48 cases of primary and 26 cases of secondary depression. The patients with secondary depression have a higher familial prevalence of alcoholism, affective disorder, and drug abuse. The groups differ somewhat on a few sociodemographic, behavioral, and attitudinal variables but are similar in symptomatology, sex ratio, onset and duration of symptoms, treatment received, and response to treatment. These results suggest that the distinction between primary and secondary depression should be retained in research that examines neurochemistry or genetics. Primary and secondary depression appear to be identical from the perspective of clinical care. Management of these patients should emphasize the diagnosis of depression rather than antecedent diagnoses.

BECAUSE PERIODS of sadness or grief are ubiquitous in human experience and because sadness is often accompanied by such typical depressive symptoms as sleeplessness or loss of interest, the concept of depression can be overinclusive and heterogeneous. Researchers interested in studying the pathophysiology or pharmacology of depression need techniques for defining depression that maximize the homogeneity of the groups under investigation, for otherwise specific findings may remain undiscovered when data are pooled and averaged. The concept of secondary depression was originally developed as one method of narrowing for purposes of research the concept of depression.

As Woodruff pointed out in one of the earliest definitions of secondary depression, the use of the natural history of illnesses to clarify nosology has impeccable historical and theoretical precedents that reach back to Sydenham (1). Drawing on a distinction originally made by Munro (2), Woodruff proposed that the broad category of depressive disorders be broken down into two mutually exclusive groups, primary depression and secondary depression, on the basis of natural history. Primary depression was defined as a depressive syndrome occurring in a patient with no prior history of any other psychiatric illness; secondary depression was defined as a depressive syndrome occurring in a patient who had an antecedent disorder. This classification system was based on the recognition that depressive syndromes are frequent accompaniments or consequences of particular psychiatric disorders, such as alcoholism, anxiety disorder, or hysteria. Woodruff and his associates anticipated that the course and prognosis of secondary depression would resemble that of the antecedent disorder and that it might require a different type of treatment than primary depression. Because of the potential influences of the various antecedent diagnoses on course and treatment, secondary depression was thought to be a less "pure" disorder than primary depression.

Perhaps because secondary depression is probably heterogeneous and therefore more difficult to study, only a modest number of investigations of this disorder have been completed since its initial definition (3–8). These investigations have suggested a number of methodologic problems inherent in its study. Should it be defined as secondary only to psychiatric disorders, or should depressions occurring in the context of other medical illnesses such as cancer also be considered as secondary? The latter alternative produces a concept of secondary depression that may be so broad as to be meaningless; consequently, the disorder should probably be defined as secondary only to psychiatric disorders. When a patient initially identified as having a primary depression later develops alcoholism, should depressions developing subsequent to the alcoholism be considered primary or secondary? To change the diagnosis to secondary seems illogical, but investigators doing biochemical or pharmacological studies

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received May 4, 1978; accepted Sept. 15, 1978.

Dr. Andreasen is Associate Professor and Dr. Winokur is Professor and Chairman, Department of Psychiatry, University of Iowa, College of Medicine, Iowa City, Iowa 52242.

This work was done as part of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression: Clinical Studies and was completed with the cooperation and participation of the Collaborative Program investigators: Martin M. Katz, Ph.D., and Gerald L. Klerman, M.D., Co-Chairmen; Robert M.A. Hirschfeld, M.D., Coordinator; Martin B. Keller, M.D., Robert W. Shapiro, M.D., and James Barrett, M.D. (Boston); Jan A. Fawcett, M.D., and William A. Scheftner, M.D. (Chicago); George Winokur, M.D., and Nancy C. Andreasen, M.D. (Iowa City); Robert L. Spitzer, M.D., and Jean Endicott, Ph.D. (New York); and Eli Robins, M.D., Paula J. Clayton, M.D., Theodore Reich, M.D., Amos Welner, M.D., and Jack Croghan, M.D. (St. Louis). This investigation was also supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-25415 from the National Institute of Mental Health.

may wish to exclude such patients from their studies in order to be sure that the sample is as homogeneous as possible. Wood and associates have also suggested that a third category, primary complicated affective disorder, may be defined to describe such cases (5). Should investigations of secondary depression further subdivide patients on the basis of their antecedent diagnoses? Since the concept of secondary depression mixes patients who have very different antecedent diagnoses, such as antisocial personality and obsessive-compulsive disorder, perhaps it should be studied on the basis of several different subgroupings, at least whenever a large enough number of patients can be accumulated. Recently Weissman and associates (6) completed an investigation that compared secondary depression in alcoholism, drug addiction, and schizophrenia and found some differences in symptom patterns.

While the usefulness of the concept of secondary depression for research has become widely accepted and various definitional issues have slowly been resolving, the clinical significance of secondary depression has received very little attention. A category that has heuristic value for purposes of research may not have heuristic value clinically. Consequently, this paper will explore the clinical utility of the concept of secondary depression. Does it differ from primary depression in symptomatology, onset, duration, and other related variables? Should it be treated in terms of cross-sectional symptomatology, or should the underlying disorder be the focus of attention and treatment?

METHOD

A subsample of patients diagnosed as having unipolar major depressive disorder were selected from the patients examined in the four centers participating in the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression (Harvard Medical School, Boston; University of Iowa College of Medicine, Iowa City; New York State Psychiatric Institute, New York; Washington University School of Medicine, St. Louis).

All patients were hospitalized and met screening criteria for a depressive or manic syndrome. A total of 150 index cases were examined by investigators from the four participating centers: 50 each at Boston and St. Louis, and 25 each at New York and Iowa City. In addition, investigators from New York and Iowa City interviewed all available first-degree relatives, a total of 88. Diagnoses of these probands were made by using the Schedule for Affective Disorders and Schizophrenia (SADS) (9) and the Research Diagnostic Criteria (RDC) (10). The first-degree relatives were interviewed with the SADS-L, a lifetime version of the SADS, and diagnosed through the RDC. All probands and available first-degree relatives were also interviewed concerning family history by investigators who used the Family History-Research Diagnostic Criteria (FH-RDC) (11). These instruments and criteria have excellent reliability.

In addition to these interviewing instruments, which provided information about course and symptoms, the patients were studied comprehensively in a variety of other ways. The Personal History for Depressive Disorders (PHDD) (G. Hogarty, unpublished data) provided a wide range of sociodemographic information, such as parental occupation, marital status, income, and education. The Symptom Checklist-90 (SCL-90) (12) was completed by each patient and provided a self-report inventory of symptomatology. These assessments were completed within the first week after admission. The SADS and RDC were updated at discharge so that new material collected since the initial interview could be incorporated, and data were also collected at this time concerning response to treatment. Data were analyzed with t test and chi-square programs from the Statistical Package for the Social Sciences (13).

RESULTS

A total of 83 patients received a diagnosis of unipolar major depressive disorder for either a current or past episode, but only 74 currently had unipolar major depressive disorder. Because we wished to study depressive phenomenology during the current episode, we included only those 74 in our investigation. Of these 74, 48 had a primary depression, and 26 had a secondary depression. Two patients whose only antecedent diagnosis was a nonpsychiatric medical illness were classified as primary. Patients who by history had a nondepressive diagnosis such as alcoholism interposed between an initial and a current depression were considered as secondary because of the possible unreliability of the depressive history. Among the patients with secondary depression, the majority of the antecedent diagnoses were personality and "acting out" disorders: Briquet's syndrome, 32%; alcoholism, 36%; drug abuse, 23%; and antisocial personality, 14%. Only a few patients had depressions secondary to disorders characterized by high levels of anxiety and internalization: panic disorder, 14%; phobic disorder, 9%; and obsessive-compulsive disorder, 5%.

The SADS interview may be subdivided into eight different scale scores on the basis of ratings on individual items (depressive mood and ideation, endogenous features, associated features, suicidal ideation and behavior, anxiety, manic syndrome, delusions/hallucinations, and formal thought disorder). Scores obtained by the patients with primary and secondary depression were strikingly similar. In order to further test the hypothesis that primary depression might have more endogenous features, the two groups were also compared on individual items from that scale (feelings of guilt, early morning awakening, loss of appetite, weight loss, poor concentration, worse in morning, loss of interest, and psychomotor retardation). The

two groups differed significantly at the .05 level (chi-square analysis, Yates's correction) only on weight loss (secondary depression higher) and on psychomotor retardation (primary depression higher). These results confirm the scale score data indicating that the two groups do not differ in any meaningful way in their amount of endogenous phenomenology.

The groups differed on a number of behavioral and attitudinal variables, based on the SADS interview and the SCL-90. Analyses were done with Student's t test. The patients with secondary depression tended to have more suicidal behavior (p=.04) but the attempts that the patients with primary depression made were more serious and life-threatening (p=.05). Unlike the data on endogenous phenomenology, these data imply that primary depression may indeed be more severe than secondary depression. The data from the SCL-90 indicate that patients with secondary depression complain of a number of self-report symptoms that probably reflect their underlying or antecedent condition. They report more somatization (p=.001), anger and hostility (p=.04), phobic anxiety (p=.01), trouble falling asleep (p=.006), and "psychoticism" (i.e., unusual or bizarre symptoms) (p=.002). This mixture of "neurotic" and nonneurotic complaints probably reflects the heterogeneity of the underlying conditions.

Table 1 summarizes family history and family study data concerning type and amount of psychiatric illness in the patients' first-degree relatives. We hypothesized that secondary depression should have a higher familial prevalence of alcoholism and personality disorders as Guze and associates (3) had observed previously. As table 1 indicates, this hypothesis was confirmed, and the two groups in fact differ rather strikingly in their familial history of illness. When the data are examined in terms of numbers and percentage of first-degree relatives who have psychiatric illness, patients with secondary depression have significantly more relatives with any diagnosis, with affective disorder, with alcoholism, and with drug abuse. Alternatively, the data may be examined in terms of the percentage of patients coming from families with a positive history of psychiatric illness, and in this instance 89% of the patients with secondary depression come from families with a more positive history for affective disorder and/or alcoholism compared with 56% of the patients with primary depression. There is a trend in the direction of patients with secondary depression having more affective disorder alone. If familial loading for psychiatric illness can be considered as an index of potential severity, then it is secondary depression that is more severe.

Table 2 compares the two groups on a number of sociodemographic and course variables. In general the two groups tend to differ in directions that are expected or that have been previously noted, but very few of these differences are statistically significant. In fact, only the difference in the father's education is statistically significant (p<.05, chi-square analysis). Some of the trends support differences noted in previous studies: patients with secondary depression are more often male, have an earlier age of onset, and have a higher divorce rate. Since those variables are frequently used to support the idea that the nature and course of secondary depression is more like that of the antecedent disorder than like that of primary depression, it is noteworthy that this investigation finds trends at most and no major statistically significant differences on these sociodemographic and course variables.

When the treatments that the two groups received and their response to treatment were examined, we found no statistically significant differences in the

**Mean age at onset was 30 years for patients with primary depression and 27 years for those with secondary depression.
***Mean duration of current episode was 26.9±29.6 weeks for patients with primary depression and 37.9±39.8 for those with secondary depression.

treatments received. Since treatment was not a variable under controlled evaluation in this study, treatment was determined by the decision of the primary ward physician, not by any of the investigators conducting the collaborative studies. Consequently, we can conclude that the clinicians responsible for the care of these patients saw no differences in them sufficient to warrant significantly different treatment approaches, although in general the patients with primary depression received slightly more ECT, antidepressants, lithium, and minor tranquilizers.

A summary of the follow-up data obtained on these patients approximately two years after their inclusion in the study indicates that a total of 31 patients with primary and 13 with secondary depression were reached and interviewed directly. In addition, 3 of those with primary and 1 with secondary depression had died. The two groups differed significantly only in terms of the number on medication at the time of follow-up (70.9% of those with primary depression still on medication 1 year later compared with only 30.7% of the secondary depression patients, $p=.03$). Trends suggest that more patients with primary depression may be working and more with secondary depression make subsequent suicide attempts, but these trends do not reach statistical significance. Otherwise the two groups are strikingly similar.

DISCUSSION

The clinical and research significance of secondary depression is not a trivial issue. Secondary depression is a very common diagnosis both on inpatient services and in outclinics. Although reports vary, the frequency of secondary depression among patients with major depression ranges from 35% in this investigation to 49% in the study of Wood and associates (5). The frequency is probably even higher in some outclinics.

The distinction between primary and secondary depression was originally developed as a way of purifying the category of depressive disorders for the purpose of research. Secondary depression was of interest only for purposes of exclusion. When it was discussed from a clinical perspective, the antecedent diagnosis was assumed to be of more clinical importance as a predictor of prognosis and response to treatment than the depressive symptomatology.

This investigation raises the possibility that that assumption may be at least partially incorrect. On most measures primary and secondary depression are more similar than they are different. Earlier investigations that found differences in sex ratio and age of onset have not been replicated, and the two groups look alike in severity of symptomatology, amount of endogenous phenomenology, most sociodemographic variables, duration of symptoms, response to treatment, and course at follow-up. There is a marked difference in familial psychopathology, with secondary depression having substantially more than primary depression, including affective disorder as well as alcoholism and drug abuse. These familial data are open to a variety of interpretations, but from a clinical perspective they tend to suggest that secondary depression is potentially more severe and familial (but not necessarily genetic) than primary depression. This investigation also suggests that secondary depression tends to be more colorful and florid, with patients making more suicide attempts, showing more "psychotic" symptoms, and complaining more of phobias, anger, difficulty falling asleep, and somatic problems. These findings imply that the picture of secondary depression may be colored by its antecedent or underlying condition.

Concerning the appropriate clinical approach to secondary depression, the results of this investigation are somewhat equivocal. They suggest provisionally that it is perhaps best to conceptualize secondary depression as an acute illness superimposed on a more chronic one. The acute symptomatology, depression, should be regarded as the immediate problem, and often the management may be no different than if it were not complicated by another underlying chronic problem. This approach is not only suggested by our data but is also the one used by our medical colleagues in most other specialties. Having one illness usually does not protect a person from developing another. In fact, the reverse is usually true, and there are often recognized relationships between medical diagnoses. Often an acute condition is a well-recognized and feared complication of a more chronic one: subacute bacterial endocarditis as a complication of rheumatic heart disease, acute leukemia as a complication of mongolism, recurrent urinary tract infection as a complication of spina bifida, pneumonia as a complication of chronic lung disease, atelectasis as a complication of asthma. Depression developing in a person with alcoholism or obsessive-compulsive disorder is quite analogous. From a clinical perspective, the most sensible course at present may be to assume that the person has two conditions, that his management is therefore somewhat more complicated and difficult than if he had only one, and that he should perhaps be treated in one way for the acute condition and in another for the chronic one.

While a clinical perspective stresses the similarities between primary and secondary depression, a research perspective continues to stress the importance of maintaining the distinction. Analogies with other medical disorders also make it quite clear that illnesses may be phenomenologically similar or identical and yet have quite a different pathogenesis. Particularly in view of significant differences between primary and secondary depression in familial psychopathology, investigators interested in the genetics, pharmacology, neurophysiology, or neurochemistry of depression should continue to exclude patients with secondary depression from study or to study them separately in order to maximize homogeneity in the group under investigation.

Personality Attributes and Affective Disorders

BY ROBERT M.A. HIRSCHFELD, M.D., AND GERALD L. KLERMAN, M.D.

To determine the personality characteristics associated with affective disorders the authors administered a battery of self-report personality inventories to a sample of hospitalized affective patients when their manifest symptoms had abated. Patients were instructed to answer according to their premorbid personalities. The personality characteristics assessed in the 73 depressive and 24 manic patients included neuroticism and extraversion from the Maudsley Personaltiy Inventory, obsessional pattern, hysterical pattern, and oral pattern from the Lazare-Klerman-Armor Personality Inventory, obsessional state and trait from the Leyton Obsessionality Inventory, and solidity, stability, and validity from the Marke-Nyman Temperament Survey. Depressive patients demonstrated more neuroticism, introversion, and obsessionality than manic patients or normal individuals. The manic patients differed from normal persons only on obsessionality.

THE ROLE of personality in depression and mania has been given considerable attention by the psychiatric community. In a recent review of psychoanalytic contributions Chodoff (1) concluded that undue interpersonal dependency and obsessionality often predispose to depression. Several newer approaches from cognitive and behavioral theory have also been applied to depression. Most notable have been works by Beck (2), Seligman (3), and Lewinsohn (4).

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977. Received May 4, 1978; accepted Sept. 15, 1978.

Dr. Hirschfeld is Chief, Depression Section, Clinical Research Branch, National Institute of Mental Health, and Coordinator, NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression, and Dr. Klerman is Administrator, Alcohol, Drug Abuse, and Mental Health Administration. Address reprint requests to Dr. Hirschfeld at NIMH, Room 10C18, Parklawn Bldg., 5600 Fishers Lane, Rockville, Md. 20857.

This work was done as part of the NIMH-Clinical Research Branch Collaborative Program on the Psychobiology of Depression: Clinical Studies and was completed with the cooperation and participation of the Collaborative Program investigators: Martin M. Katz, Ph.D., and Gerald L. Klerman, M.D., Co-Chairmen; Robert M.A. Hirschfeld, M.D., Coordinator; Martin B. Keller, M.D., Robert W. Shapiro, M.D., and James Barrett, M.D. (Boston); Jan A. Fawcett, M.D., and William A. Scheftner, M.D. (Chicago); George Winokur, M.D., and Nancy C. Andreasen, M.D. (Iowa City); Robert L. Spitzer, M.D., and Jean Endicott, Ph.D. (New York); and Eli Robins, M.D., Paula J. Clayton, M.D., Theodore Reich, M.D., Amos Welner, M.D., and Jack Croghan, M.D. (St. Louis).

In contrast to these predispositional theoretical approaches, two alternate formulations about the relationship of personality and depression may be considered:

1. Certain personality features and certain psychiatric disorders may be manifestations of the same underlying process, be they genetic, developmental, familial, or other. That is, a personality trait may represent a subclinical expression of a psychiatric disorder (e.g., cyclothymia and bipolar disorder). If this trait has a familial or genetic basis, we would expect to find increased levels of the trait in relatives, both affected and nonaffected, as well as in patients.
2. Personality qualities may be altered by the experience of the affective disorder. Chronic diseases, either medical or psychiatric, often lead to changes in individual personality patterns. The extent to which this may occur in acute, chronic, and current depressions is at present unknown.

In spite of the considerable clinical and theoretical interest, surprisingly little controlled empirical research has been conducted in this area. Probably the major reason for this is methodologic difficulties, especially the lack of reliable and valid assessment procedures for diagnosis and for personality. Relatively few empirical studies have addressed the association of personality variables and depressive syndromes, and even fewer have dealt with mania. Interpretation of even these studies is difficult due to a lack of standardized diagnostic assessment tools and variation in personality variables.

A necessary first step in testing these or other formulations about the relationship between personality and depression is careful objective assessment of personality traits in sufficiently large samples of depressed patients. In this paper we describe a study addressing this issue: specifically, ascertainment of personality characteristics in a carefully diagnosed sample of patients with affective disorders.

PATIENT SAMPLE AND METHOD

Our sample included 119 depressed inpatients at four major university hospital centers (Boston, New York, St. Louis, and Iowa City) who were comprehensively assessed using the Schedule for Affective Disorders and Schizophrenia (SADS) (5) and the Research Diagnostic Criteria (RDC) (6) in addition to sociodemographic and other measures. The sample included 41 males and 78 females, had a mean age of

34, and was predominantly Caucasian. Seventy-three patients were diagnosed as having a major depressive disorder, 24 as having a manic or hypomanic disorder, and the rest as having various other diagnoses, including minor depression, schizophrenia, schizo-affective disorder, alcoholism, and drug abuse.

A research assistant administered a battery of self-report personality inventories to the patients near the time of hospital discharge when their manifest symptoms had largely abated. Because we were seeking estimates of premorbid personality levels, the research assistant explicitly instructed the patients to disregard their current state of illness and to answer the questions according to their usual self. The rationale for this procedure comes from independent studies by Kendall and DiScipio (7), Philip (8), and Foulds (9), which demonstrated that scores similar to those made during asymptomatic periods may be obtained from symptomatic depressed patients.

The personality inventories used were the Maudsley Personality Inventory, the Lazare-Klerman-Armor Personality Inventory, the Marke-Nyman Temperament Scale, and the Leyton Obsessional Inventory. The Maudsley Personality Inventory (MPI) (10) measures extraversion and neuroticism. The Lazare-Klerman-Armor Personality Inventory (11, 12) assesses three psychoanalytic personality patterns—oral, obsessional, and hysterical. The Marke-Nyman Temperament Inventory (MNT) (13) assesses three of the four Sjöbring personality factors: validity, stability, and solidity. Although relatively unknown in the United States, it has been used extensively in Europe. A version suitable for American subjects was developed by Barrett and Nyman (14). The Leyton Obsessional Inventory (15) measures two aspects of obsessionality: symptoms (as in obsessional neurosis) and trait (as in obsessional character).

RESULTS

The depressive patients differed substantially both from the manic patients and from the published American norms for each of the scales (see table 1). The depressive patients scored significantly higher on introversion, neuroticism, obsessionality, solidity, and stability and significantly lower on validity than the norms in the literature. The manic subjects differed from the norms only on obsessional state and obsessional trait.

In order to facilitate interpretation of these findings, a principal component factor analysis and rotation was performed on the 10 × 10 matrix of correlations of scale scores. Three factors emerged, accounting for 73% of the total variance. The factor-loading matrix was then subjected to a normal varimax rotation (see table 2). Examination of the resultant factor-loading matrix reveals that factor 1 is representative of the neuroticism, validity, orality, and obsessional state scales and might be deemed "nonspecific neuroticism and emotional weakness." Factor 2 represents solidity, hysterical pattern, extraversion, and stability and might be labeled "general sociability and suggestibility." The third factor clearly represents obsessionality. Scores were calculated for each of the depressive and manic patients. When the groups were compared using t tests, the depressive patients scored much higher than the manic patients on nonspecific neuroticism and emotional weakness ($p < .0001$), slightly lower on general sociability and suggestibility ($p < .07$), and very similar on obsessionality.

Although we had specifically instructed the patients to disregard the experience and effects of their current illness, the possibility remained of contamination of

the trait assessments by clinical state. So we readministered most of the personality battery two years later to those subjects who at index had suffered from either a major depressive disorder or manic disorder and who at follow-up were asymptomatic or back to their usual self. Of the 73 major depressive patients, 15 who were willing to complete the questionnaire met these criteria. The index episode personality scale scores of this subgroup of 15 were very similar to those of the whole major depressive group, which suggests that they are representative. The follow-up scores for seven of the eight measures were stable over this two-year period, with only the neuroticism score changing a great deal. Pairwise t tests and Pearson product-moment correlation coefficients provided statistical confirmation of this (see table 3).

Of the 24 manic patients, only 4 who met the criteria for the follow-up returned the questionnaire, so statistical analysis was not feasible. The result was some shifts in scores for these 4 patients; however, none of the follow-up scores approached those of the depressive patients.

DISCUSSION

Our empirical findings strongly support the notion that there are abnormalities in the personalities of patients with affective disorders. These findings agree with prior empirical work. In two studies of recovered hospitalized depression patients Kendall and DiScipio (7, 16) reported mean scale scores very similar to our study's scores on neuroticism, extraversion, obsessional state, and obsessional trait. Paykel and Prusoff (17) found nearly identical mean obsessional, hysterical, and oral factor scores in their study of 176 depressive patients. With the exception of the mean score on the stability scale, the mean scores on the Sjöbring dimensions of solidity and validity of the 62 recovered depressive patients in Coppen's study (18) were also very similar.

Further support for the validity of these findings is provided by comparing the intercorrelations among the scales in this study with those of other studies in the literature; the correlation coefficients between the prior studies and this one are nearly identical (16, 17, 19).

Overall, the results suggest that depressive patients are more likely to break down under stress, have less energy, are more insecure and sensitive, tend to worry more, are less socially adroit, are more needy, and are more obsessional than normal individuals. Manic patients, on the other hand, have much more normal personality profiles, at least as far as the assessed dimensions indicate. However, they are significantly more obsessional than normal individuals.

Our findings are also consistent with the major psychological theories of depression. Chodoff (1) concluded that depression-prone people are inordinately and almost exclusively dependent on narcissistic supplies derived directly or indirectly from other people for maintenance of their self-esteem. Their frustration tolerance is low, and they may employ various techniques—submissive, manipulative, coercive, piteous, demanding, or placating—to maintain their desperately needed relationships with external or internalized objects that provide these supplies.

In the cognitive approach put forth by Beck (2, 20) depressive patients are seen as possessing an enduring cognitive set consisting of negative attitudes and beliefs regarding the self, the world, and the future. This set causes the depression-prone person to distort his or her interpretations of experience so as to see and expect defeat, frustration, and deprivation and to regard himself or herself as inadequate, undesirable, and unworthy. Such people are highly sensitive to situations that reinforce these negative self-attitudes.

Another cognitive theory is that of learned helplessness, which was proposed by Seligman (21). He noted that if dogs are unable to prevent or alter an aversive stimulus (e.g., an electric shock), they soon elicit behavior that is strikingly similar to that of human depressive individuals, including withdrawal, apathy, and reduction in goal-directed behavior. Once conditioned, this behavior is very resistant to change, even when opportunities to avoid the aversive stimulus become available. This observation led to the development of the learned helplessness theory of depression. Seligman notes that six of the major symptoms of learned helplessness are parallel to those found in depression: 1) lowered initiation of voluntary responses, 2) negative cognitive set, 3) time course, 4) lowered aggression, 5) loss of appetite, and 6) physiological changes.

The behavioral approach to depression emphasizes the deficient instrumental behaviors of the depressive individual. Lewinsohn (4), for example, has shown that instrumental behaviors such as social skill (i.e., the ability to emit behaviors that are positively reinforced by others) are significantly less developed in depressive patients than in others. He postulates specifically that a reduction in the rate of positive behavioral reinforcements is the cause of depression. Low self-esteem is a consequence of the lack of such reinforcements. The interaction of impaired instrumental be-

havior and a low rate of positive reinforcements tends to perpetuate low self-esteem and dysphoria. Thus, the depressive individual is less able to influence others to receive positive attention from them.

The excessive dependency on others described in psychoanalytic theory, the negative attitudes and learned helplessness of cognitive theory, and the deficient instrumental behaviors described in behavior theory are all consistent with the profile emerging from this study. That is, the depressive is introverted, lacking in self-confidence, unassertive, dependent, pessimistic, and perceives himself or herself as inadequate.

In order to examine the utility of these different approaches, one must determine what causes the changes noted in depression. The psychoanalytic approach puts primary emphasis on the satisfaction of instinctual drives and postulates specifically that abnormalities exist in the depressive person's drive system. The cognitive theorists propose that the abnormal cognitive set derived from early experience is the fundamental problem and that affective changes are secondary. Obviously, the behavioral approach considers behavioral deficits as the source of the affective and cognitive changes.

There are fewer theories about mania and bipolar illness, but one that is quite consistent with the reported results is that proposed in the mid-1950s by a group of Washington psychoanalysts, including Mabel Blake Cohen, Robert Cohen, and Frieda Fromm-Reichmann (22). In essence, they proposed that various childhood experiences led to an adult character in manic individuals that was extraverted and outward-directed, in addition to well adjusted. However, close scrutiny revealed a few extremely dependent relationships, in which there was a demand for love without reciprocity that stemmed from a fear of abandonment due to internal emptiness.

Our results are consistent with this hypothesis, but our methods are insufficient to test the full extent of this theory. Several studies (23–26) done in the general time frame of the seminar did tend to support these findings. More recently, Perris (27) found that bipolar depressive persons had more normal personality profiles than unipolar depressive individuals.

We have reported here on the personality characteristics of manic and major depressive patients without further subtyping diagnoses. With the depressive disorders in particular, there is a large amount of genetic, clinical, and biochemical evidence that depressive disorders are heterogeneous. Therefore, it would be expected that the personality profiles of various depressive disorders would differ. Documentation of such differences would provide further evidence for the validity of the heterogeneity theory of affective disorders. Insufficient cell sizes have prevented definitive analysis of possible differences among depressive subtypes, but future studies are planned with cell sizes sufficiently large to allow such analyses.

EDITORIALS

The APA Model Law on Confidentiality

THE MODEL LAW ON CONFIDENTIALITY, prepared jointly by the APA Task Force on Confidentiality of Children's and Adolescents' Clinical Records and the APA Committee on Confidentiality and published elsewhere in this issue, is designed to serve as a prototype for potential enactment in the individual states. The model is broadly drawn; it applies to all medical, psychiatric, and social service records. Although some provisions may be considered controversial, each jurisdiction can decide for itself which are desirable and/or enactable given the local legislative and professional ambience.

The issues of privacy, confidentiality, and the privilege of communications between physician and patient are in the public eye because of the impact of Watergate, the Ellsberg case, the report of the Privacy Protection Study Commission, the proliferation of linked data banks, and the encroachments on privacy by insurance carriers. Several independent groups have fashioned model laws on confidentiality. We believe the APA Model Law is at present most sophisticated from the point of view of our profession.

A law on confidentiality has a much broader reach than does a law on privilege; the latter applies only to doctor-patient privilege in judicial, administrative, and legislative proceedings. Also, most privilege laws have so many exceptions as to be of limited value. A law on confidentiality, on the other hand, must consider the constitutional right to privacy, professional codes of ethics, confidentiality of therapist-patient communications, and rules and regulations regarding hospital records and other health care and social service information. The responsibilities of computer-bank technicians, researchers, insurance companies, and employers must be articulated to protect the privacy of the individual and yet recognize the valid requirements of society vis-à-vis scientific advance and business technology.

The APA Model Law on Confidentiality is a highly technical document and will require expert legal counsel to "translate" some of its provisions. For example, Section 2 on "Definitions" provides the basis for confidentiality to a degree that becomes apparent only as one studies carefully the remainder of the law. Section 3 provides for informed consent in such a way that blanket consent forms cannot be used by insurance carriers; also, patients may revoke previous consent, and unauthorized redisclosures are prohibited. The insurance industry objects to these provisions on the basis of cost, but the public increasingly demands such protection. Several reviewers of the Model Law have objected to the 12-year age of consent, believing this to be too low; others point out that age 7 is stipulated in federal regulations concerning human experimentation. Again, each jurisdiction can decide the specific age of consent according to a local consensus.

Section 4, "Disclosures Without Authorization," is a particularly subtle section providing confidentiality guidelines in situations of training, audit, accreditation, billing, medical emergency, dangerousness, and litigation. Much case law and practical experience has been encompassed in drawing an optimal line between the needs for confidentiality and the legitimate needs of a complex society for information. Paragraph 4 (c) allows breaches of confidentiality for reporting child abuse and also to protect a patient or an intended victim from a dangerous act at

the therapist's sole discretion. This is much different from the "duty to warn" interpreted to have been mandated by the *Tarasoff* decision.

Paragraph 4 (e), "Patient/Client—Litigant Exception," protects communications between a therapist and patient in litigation. Provision is made for testimony by an examining clinician rather than the therapist unless there are unusual circumstances; similarly, the content of the therapist-patient communications is protected unless a compelling need for disclosure is proven. In contrast to most current laws, the balance is changed toward protecting patient-therapist communication. Provision is also made to allow a clinician to defend himself in case of a malpractice action. Similarly, disclosures from a court-ordered psychiatric examination are limited to the patient's clinical condition, thus precluding using the professional examination for a police function.

Of particular current relevance is Section 7, "Prescriptions," which provides that prescriptions constitute confidential information and are thus subject to the Act, but that state and federal drug regulations and laws must be obeyed.

Provisos for confidentiality in a research context have been resisted by epidemiologists and statisticians. The Model Law draws the line at removing patient-identifiable confidential material from the facility providing service. Most statistical and epidemiological research can be carried out through nonidentifiable data; research access to on-site identifiable data must be pre-reviewed by an appropriate research review committee.

Penalties for unauthorized disclosures (Sections 10 and 11) are intended to underline the responsibility of professional and clerical personnel to recognize their responsibilities to maintain the confidentiality of patient records. There is some controversy over whether punitive as well as civil penalties are in order. The APA committees believe that punitive damages for willful or grossly negligent violations of confidentiality are reasonable, but, again, local jurisdictions can modify these stipulations according to their own judgment. Hospital administrators will view provisions for damages with apprehension, but in our information-hungry society the balance of forces must emphasize the importance of privacy, and all personnel must be educated as to their responsibilities to protect the interests and privacy of the patient. The Denver State's Attorney demonstrated that the Factual Services Bureau fraudulently obtained sensitive medical information from hospital and private office charts by impersonating medical personnel. Punitive penalties would help prevent such criminal activity.

Another innovative and perhaps controversial section (Section 12) deals with access by patients to their clinical records. Current federal and state legislation as well as case law provides for access by consumers to data from which decisions modifying their lives may be made by others, such as credit agencies. However, when a physician determines that disclosure of clinical data would be detrimental to the patient, a hierarchy of procedures is established by which a patient may contest that determination. A "clinical mediator" clinician may be appointed by the patient to review the material; if he agrees with the original clinician that the information should not be disclosed, the persistent patient may go to court for a hearing and, if necessary, an *in camera* review of the data.

Another precaution regarding such disclosures is provided in Section 14, "Personal Notes." The concept of a work record of an attorney provides that a lawyer's personal notes regarding a client's case are not "discoverable" in the interest of establishing a circumstance under which a citizen may be free to disclose his troubles to a lawyer in his democratic self-interest. This concept is extended to the work record of a clinician, so that sensitive third-party information can be protected, as well as his own speculations, impressions, and research data. Thus a chilling factor to his research and clinical interests is avoided. This is a pioneer concept and will have to stand the test of time.

Section 15 provides for confidentiality of insurance records. There have been many instances of breach of privacy by employers and/or clerical personnel. Provision is made for bypassing the employer's personnel office and direct communication with the insurance companies. Section 16 prohibits unauthorized redisclosure by the insurance companies to other agencies such as the Medical Information Bureau. The insurance industry may well resist the enactment of these two

sections and in most states may prevail, as they did this past year in Illinois when a Confidentiality Act containing most of the provisions of the APA Model Law was enacted. It is hoped that implementation of the recommendations of the Privacy Protection Study Commission by Congress will neutralize this aspect of insurance applications and claims.

Sections 17 and 18 formulate guidelines for state, county, local, and federal agencies in performing audits, inspections, and investigations. There have been many instances in which auditors and police agencies have demanded access to sensitive records, thereby destroying the effectiveness of psychiatric and drug-abuse clinics. The principle has been established that funding per se does not entitle complete access to identifiable clinical records. Government agents must become educated to their responsibility to protect the privacy of citizens, including those who receive agency largesse.

Similar problems exist with data processing. Linkages of various data banks allow the profiling of private citizens to a surprising extent through use of Social Security or driver's license numbers. Paragraph 17 (c) has been designed to help counter such unauthorized invasions of privacy. At present most government agencies will resist such attempts at regulation, but, again, it is a matter of persistent education of the consumer, the profession, and the bureau.

In some states the APA Model Law will represent such a radical advance that it will not be enactable at present. As already noted, in Illinois most of the model has been enacted, even though it was necessary to omit the section dealing with insurance matters because of the effectiveness of the insurance industry lobby in order to save the remainder of the bill. Similarly, it was necessary to provide access to the state's attorneys for investigative purposes, but with the proviso that unauthorized redisclosure is prohibited. It is also of interest that similar legislation was recently introduced into Congress as S 3450 under the joint sponsorship of Senators Javits, Muskie, and Ribicoff.

Because of the public's interest in preserving privacy, it has been predicted that in ten years all states will have privacy laws. Psychiatrists, because they are particularly sensitive to confidentiality as a prerequisite to the effectiveness of their work, are among the leaders in effectuating such legislation. The APA Model Law incorporates our expertise. Most lawyers will be opposed to many of its provisions. Just as we require confidentiality for our work, lawyers require complete discovery of information. Our professional interests are antithetical but are subject to education, negotiation, legislation, and litigation. It is in the interest of society, our patients, and our profession that confidentiality laws be enacted in each state. The Model Law can serve as a prototype lending itself to local modifications. The APA Committee is available for consultation.

JEROME S. BEIGLER, M.D.

Dr. Beigler is Chairperson, APA Committee on Confidentiality, and President, Illinois Psychiatric Society, 55 East Monroe St., Suite 3510, Chicago, Ill. 60603.

A Note of Appreciation

"WHEN IT COMES to the need for praise," wrote a recent reviewer in the *Times Literary Supplement,* "authors. . .like it applied not with a trowel but a crane." The Editor's own introspections long ago convinced him of the truth of that dictum, and it is perhaps one of the more painful aspects of his job that, as the ultimate arbiter of manuscripts submitted to the *Journal,* he must disappoint so many aspiring writers. The burden of his task is, however, immeasurably lightened not only by the collective wisdom of his Managing Editor, his Associate Editors, and his Editorial Staff, but by the help of the multitude of expert reviewers throughout the country who selflessly give of their knowledge and time. The latter, indeed, work silently behind the scenes, demanding no praise, requiring no recognition, asking no recompense other than the satisfaction of helping to maintain the *Journal's* scientific standards. "Mute inglorious Miltons" they would remain were it not possible once a year for the Editor and his staff to recognize them by name in these pages. And so, as the new year dawns, we give heartfelt thanks for their invaluable contributions.

1978 has seen the editorship change hands, and the Editor would like to express his deep appreciation to the Editor Emeritus, the Managing Editor, the Associate Editors, and the *Journal* staff for making the transition easy and pleasurable. The entire Editorial Staff, furthermore, must acknowledge its considerable indebtedness to our Medical Director, Dr. Melvin Sabshin, for his unfailing help and understanding. Our sincere thanks for their continued support and interest go also to Drs. Lee Gurel, Donald W. Hammersley, Carolyn Robinowitz, Jeanne Spurlock, Jack White, and Henry H. Work; to Mses. Nancy Frey and Jean Jones; and to Mssrs. Herbert M. Gant, Raymond M. Glasscote, Charles B. Kurta, and Robert L. Robinson.

Finally, we extend our warmest wishes to all our colleagues for a joyous, successful, and peaceful 1979.

J.C.N.

BRIEF COMMUNICATIONS

Factors Related to Tardive Dyskinesia

BY GUY CHOUINARD, M.D., M.SC.(PHARMACOL.), LAWRENCE ANNABLE, DIP.STAT., ANDRÉE ROSS-CHOUINARD, M.D., AND JOANNIS N. NESTOROS, M.D.

The authors found a 31% incidence of tardive dyskinesia among 261 schizophrenic outpatients treated with neuroleptics. Multiple linear logistic regression analysis revealed a higher incidence of tardive dyskinesia among elderly patients, those with longer records of hospitalization, those for whom neuroleptic medication had little therapeutic effect, and those treated with fluphenazine. Patients manifesting tardive dyskinesia tended to have fewer parkinsonian symptoms than those without the disorder, especially when tremors and akathisia were excluded from consideration. Multiple linear regression analysis indicated that brain-damaged patients and male patients were more susceptible to severe forms of the disorder, even though these factors were not implicated in its initial appearance.

TARDIVE DYSKINESIA is a hyperkinetic syndrome of extrapyramidal nature associated with neuroleptic drug use (1–3). It is characterized by involuntary repetitive and purposeless movements varying in localization and form but commonly involving the mouth, lips, tongue, and jaw (bucco-linguo-masticatory dyskinesia) and at times by choreoathetoid movements of the neck, trunk, or limbs. These movements are usually intensified by emotional tension or by voluntary movements of other muscle groups. They are reduced in intensity by sleep or drowsiness. Neuroleptic drugs that are causing the syndrome can temporarily reduce the dyskinesia, and the abnormal movements may become more severe or appear for the first time after drug withdrawal or dose reduction (4). Antiparkinsonian drugs fail to reduce the dyskinetic movements and can aggravate or uncover the tardive dyskinesia (5). In many patients the syndrome is irreversible; in others it can sometimes be reversed by discontinuing the neuroleptics (6). When the condition is life-threatening, as in rare cases of dyskinesias of the esophagus or diaphragm, piperazine-like neuroleptics (fluphenazine or haloperidol) can be given and anticholinergic drugs (antiparkinsonian or others) avoided.

Recent studies have shown that tardive dyskinesia occurs with alarming frequency among patients treated with neuroleptics (7, 8). Fann and associates (7) found that 36% of a sample of 204 patients treated with neuroleptics manifested the syndrome. At the present time, there is no treatment of tardive dyskinesia that is effective over a long period of time; most efforts are directed toward its prevention.

The Allan Memorial Institute maintains a special follow-up clinic for the long-term maintenance treatment of schizophrenic outpatients. The present study was designed to evaluate the incidence and severity of tardive dyskinesia among 261 patients from this population and to determine the relationship of the syndrome to various other factors. Whereas most previous surveys of tardive dyskinesia were conducted in long-term wards of mental hospitals, this study dealt with a population of schizophrenic outpatients.

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2–6, 1977. Received July 7, 1977; accepted Jan. 10, 1978.

Dr. Chouinard is Assistant Professor, Department of Psychiatry, McGill University, Allan Memorial Institute, and Psychiatrist and Pharmacologist, Research Department, Hôpital Louis-H. Lafontaine, 7401 Rue Hochelaga, Montreal, Que., Canada H1N 3M5. He is also Professor, Institut National de la Recherche Scientifique-Santé, Montreal. Mr. Annable is Assistant Professor, Department of Psychiatry, McGill University, and Biostatistician, Institute National de la Recherche Scientifique-Santé, Hôpital Louis-H. Lafontaine. Dr. Ross-Chouinard is Neurologist, Hôpital Hôtel-Dieu de Montréal, and Lecturer, McGill University. When this work was done Dr. Nestoros was a resident in psychiatry, Allan Memorial Institute. He is now Assistant Psychiatrist, Allan Memorial Institute.

The authors gratefully acknowledge the help of M. Kropsky, M.D., T. Petitjean Roget, who performed the computations, and Diane Ross and Marilyn E. Levy.

METHOD

Patients are accepted in the special follow-up clinic after the primary hospital diagnosis of schizophrenia is confirmed by the psychiatrist in charge of the clinic. The diagnostic criteria used are similar to those of the National Institute of Mental Health–Psychopharmacology Service Center Collaborative Study (9). Schizophrenic patients who are not likely to need long-term pharmacotherapy are not accepted in the clinic. During the two years before this study pharmacotherapy was under strict control, and the following principles were applied: the minimum therapeutic dose was given; a single neuroleptic was prescribed whenever possible; drugs were administered in a single daily dose or twice-daily regimen; procyclidine (Kemadrin) was the only antiparkinsonian drug used; attempts were made to withdraw the antiparkinsonian after three months of treatment; fluphenazine enanthate, an injectable long-acting drug, was given to patients who were resistant to other neuroleptics, those who could not be relied upon to take medication, and those with frequent relapses; fluphenazine hydrochloride was the only piperazine-type drug given orally; polypharmacy was avoided and antidepressant drugs, minor tranquilizers, and hypnotics were not prescribed; and, finally, medication was reviewed each time the patient came to the clinic.

The patients were examined by a neurologist who had not seen them before in random order on the day they came for their regular visit to the clinic. All patients were examined except for a small percentage (less than 5%) who repeatedly failed to keep appointments. The neurologist completed a structured medical questionnaire,[1] carried out a complete neurological examination, and rated each patient for the presence and severity of tardive dyskinesia and other extrapyramidal symptoms. The presence of tardive dyskinesias was assessed according to a standard procedure that included the following routine neurological tests: 1) the patient's spontaneous behavior was observed while seated, standing, or walking, 2) since abnormal movements are increased by voluntary movements of other muscle groups, the oral-facial region was observed while the patient carried out the pronation-supination tests of both hands as fast as possible and performed rapid alternate movements of both wrists and the finger-nose-finger test, 3) the patient was asked to walk without shoes so that any choreoathetoid movements of the limbs could be noted, and 4) the patient was asked to copy a spiral with both hands and to sign his or her name (since the test is performed under emotional tension, this procedure may activate dyskinetic movements and thus sometimes uncover covert dyskinesias). In doubtful cases, the patient was asked to open his or her mouth while performing the pronation-supination and alternate movement tests so that the tongue could be observed. Questionable cases of tardive dyskinesia were not considered to be positive.

Dyskinetic movements were rated according to frequency and amplitude on a 4-point scale (0–3) as follows: 0=absent, 1=mild but clearly present, 2=moderate, and 3=severe. Abnormal movements in the lingual, masticatory, and facial-labial areas and the trunk and extremities were rated separately.

Other extrapyramidal symptoms were also rated on a modified version of a specially designed extrapyramidal rating scale (10). The following items were evaluated: expressive automatic movements (facial mask and speech), bradykinesia, rigidity of limbs, gait and posture, tremor (of limbs, head, chin, and tongue), akathisia, increased salivation, and dystonia. Both spontaneous tremors and those manifested when the patient extended both arms forward with palms down and eyes closed or performed the spiral test and handwriting were evaluated. Each item was rated on a 6-point scale ranging from normal to extremely severe.

In the same visit the patient was seen by one of three psychiatrists who rated the therapeutic response to treatment on a 5-point scale (11) and overall severity of illness on a 7-point scale (11). The neurologist and psychiatrists did not have access to each others' findings.

RESULTS

The study population consisted of 261 schizophrenic outpatients, 138 male and 123 female, ranging in age from 19 to 67 years. Table 1 shows the mean and standard deviation for the age, length of neuroleptic treatment, neuroleptic dose (converted to chlorpromazine units [12]), clinical global impression (CGI) of overall severity of illness, and CGI therapeutic effect for male and female patients separately and for both sexes combined. Table 2 shows the percentages of patients with tardive dyskinesia and parkinsonian symptoms, those being treated with antiparkinsonian medication and fluphenazine, and those with a history of ECT treatment, insulin treatment, brain damage, alcoholism, antidepressant treatment, and hospitalization.

Three kinds of statistical analysis were performed on the data. In each analysis the variable for tardive dyskinesia was regressed against the following variables: age, number of years treated with neuroleptics, length of previous psychiatric hospitalizations, current dosage of neuroleptics (converted to chlorpromazine units), current fluphenazine treatment, total score for parkinsonian symptoms, antiparkinsonian dosage, number of ECT treatments, number of insulin treatments, presence of brain damage, alcoholism, history of antidepressant treatment, CGI overall severity of illness, and CGI therapeutic effect.

[1]The medical questionnaire covered the following items: 1) family history of mental disease, epilepsy, abnormal movements or tics, or any neurological disease, 2) history of previous admission for or investigation of neurological disorder, brain surgery, head trauma (with or without skull fracture), meningitis, or coma, and history or presence of abnormal movements, tics, epilepsy, or venereal disease, 3) abnormal laboratory results (VDRL or EEG), 4) history of loss of consciousness, headache, visual trouble (decreased vision), loss of balance or difficulty walking, or difficulty swallowing or talking, and 5) history of alcoholism or drug abuse (LSD, barbiturates, etc.).

TABLE 1
Characteristics of 138 Male Patients and 123 Female Patients in Study Population

Characteristic	Males Mean	Males SD	Females Mean	Females SD	Total Mean	Total SD
Age (years)	38.3	11.0	44.2	11.1	41.1	11.4
Years of neuroleptic treatment	8.8	5.7	10.7	5.8	9.7	5.8
Neuroleptic dose (chlorpromazine units)*	425.0		300.0		400.0	
CGI (in general)	4.6	0.9	4.5	0.9	4.5	0.9
CGI (therapeutic effect)	1.6	0.9	1.7	0.9	1.6	0.9

*Median dose given because the distribution of neuroleptic dosages was skewed (range=0–5500 chlorpromazine units/day). Neuroleptic medications were converted to chlorpromazine units according to the equivalency given by Davis and Cole (12). Fluphenazine enanthate was converted to chlorpromazine units on the basis of an equivalency of a dose of 25 mg I.M. every 2 weeks to 300 mg chlorpromazine daily.

TABLE 2
History and Presence of Tardive Dyskinesia or Parkinsonian Symptoms in 138 Male Patients and 123 Female Patients in Study Population

Factor	Males (%)	Females (%)	Total (%)
Tardive dyskinesia	29.0	32.5	30.7
Parkinsonian symptoms	71.0	59.3	65.5
Antiparkinsonian treatment	60.9	56.9	59.0
Fluphenazine treatment	47.8	30.9	39.9
ECT treatment	47.8	59.3	53.3
Insulin treatment	4.5	8.8	6.5
Brain damage	24.6	17.1	21.1
History of alcoholism	17.4	3.3	10.7
History of antidepressant treatment	23.2	31.7	27.2
Previously hospitalized	86.2	90.2	88.1

TABLE 3
Variables Significantly Related to Presence of Tardive Dyskinesia According to Stepwise Logistic Regression Analysis

Variable	Significance
Age	p<.001
Days in hospital	p=.03
CGI therapeutic effect	p=.05
Fluphenazine treatment	p=.03
Parkinsonism total score (negatively related)	p=.06*

*p=.03 when score for tremors is excluded from parkinsonism total score; p=.02 when scores for tremors and akathisia are excluded from parkinsonism total score.

Variables Predicting Incidence of Tardive Dyskinesia

Patients were coded 1 or 0 according to whether tardive dyskinesia was present or not; a regression analysis using the linear logistic model (13) related other variables to the probability of the patient's manifesting tardive dyskinesia. This analysis was carried out on all 261 patients by a computerized stepwise inclusion procedure (14), which first determines the single most important characteristic in predicting the incidence of tardive dyskinesia, then the second most important variable given that the first has been included in the equation, and so on. Table 3 shows the five variables that, when entered sequentially, made statistically significant ($p < .05$) contributions to the regression relationship. The variable most related to the incidence of tardive dyskinesia was age, which was highly significant ($p<.001$). Then followed length of time spent in a psychiatric hospital, score for CGI therapeutic effect (a high score indicates little improvement, i.e., there tended to be a greater incidence of tardive dyskinesia among patients with little therapeutic improvement), fluphenazine treatment, and, finally, the total score for parkinsonian symptoms, which was related inversely to tardive dyskinesia (i.e., patients with fewer parkinsonian symptoms tended to have a higher incidence of tardive dyskinesia). When the score for tremors or the scores for both tremors and akathisia are excluded from the total score for parkinsonian symptoms, the inverse relationship between tardive dyskinesia and parkinsonian symptoms becomes more pronounced (see table 3). A test of goodness of fit of the model showed the fit to be satisfactory ($\chi^2=1.6$, df=4, p=.8).

TABLE 4
Variables Contributing Significantly to Multiple Regression Relationship with Total Score for Tardive Dyskinesia,* As Entered by Stepwise Inclusion

Variable	Significance	Multiple Correlation Coefficient	Partial Correlation Coefficient
All patients included (N=261)			
Age	p<.001	.29	.29
CGI therapeutic effect	p=.003	.34	.19
Parkinsonism total score (negatively related)	p=.026	.37	−.14
Fluphenazine treatment	p=.013	.39	.15
Days in hospital	p=.050	.41	.12
Sex (male)	p=.049	.43	.12
Only tardive dyskinesia patients (N=80)			
Brain damage	p=.003	.33	.33
CGI therapeutic effect	p=.045	.39	.23
Age	p=.089	.43	.19
Parkinsonism total score (negatively related)	p=.079	.47	−.20
Sex (male)	p=.077	.50	.20

*Scores for tremors and akathisia are excluded from total score for parkinsonian symptoms.

Variables Predicting Severity of Tardive Dyskinesia

This analysis related the severity of tardive dyskinesia, as measured by the total score, to the other variables by the usual multiple linear regression model. A first analysis was carried out on all 261 patients by a computer program using a stepwise inclusion procedure (15). Table 4 shows the six variables that, when entered sequentially, were significantly related to the total score for tardive dyskinesia. The same five variables found to be related to the incidence of tardive dyskinesia were also related to the severity of the disorder, although there is some change in their relative importance. Again, the inverse relationship between tardive dyskinesia and parkinsonian symptoms was more pronounced when the score for tremors and aka-

thisia were excluded from the parkinsonism total score. In addition, the sex of the patient enters the relation, with male patients tending to show more severe forms of the condition than female patients. The six variables included in the equation account for 18.5% of the total variation in the scores for tardive dyskinesia among the 261 patients.

Finally, we repeated this analysis including only those 80 patients who had tardive dyskinesia (table 4). This analysis revealed that among the patients with tardive dyskinesia, those with previous brain damage tended to have more severe forms of the disorder.

DISCUSSION

Recent surveys show a higher incidence of tardive dyskinesia than was first reported. In this study, tardive dyskinesia was found to be present in 31% of a population of 261 schizophrenic outpatients treated by neuroleptics; this percentage is similar to that reported by Fann and associates (7). Age was clearly the most important contributory factor; older patients were more susceptible to tardive dyskinesia. It has also been our clinical experience that the older the patient is when first started on neuroleptics, the sooner he or she is likely to develop the syndrome. This would indicate a need for caution when prescribing neuroleptics to the elderly patient. A 1977 study (16) suggested biochemical changes in the striatum with aging, and it might be hypothesized that these changes could favor the appearance of tardive dyskinesia.

Among patients of the same age, those for whom neuroleptic treatment was producing little therapeutic effect were more likely to present severe forms of tardive dyskinesia. When linked with the finding on age, this suggests that in some cases it may be beneficial to withdraw neuroleptics from older patients who are responding poorly to treatment.

Crane (2, 4) has reported that severe tardive dyskinesia is seldom observed in patients with severe parkinsonism, and vice-versa. Our findings support this, especially when tremors and akathisia are not included among the other parkinsonian symptoms. These two symptoms were excluded because our clinical experience has shown that a patient with tremors or akathisia may manifest tardive dyskinesia, whereas a patient with akinesia or rigidity seldom does. There tended to be a high incidence of tardive dyskinesia among patients being treated with fluphenazine (oral or enanthate). Although fluphenazine was the only piperazine drug given to these patients, one might expect this finding would also apply to the other piperazine-like drugs, which are responsible for a higher incidence of parkinsonian symptoms. It is possible that the hyperkinetic parkinsonian symptoms of tremor and akathisia are precursors of hyperkinetic symptoms of dyskinesia. Thus, these symptoms could be expected to coexist with dyskinetic symptoms in patients shifting from one syndrome to the other. In contrast, the hypokinetic parkinsonian symptoms of rigidity and akinesia could reduce or cover the expression of dyskinesia.

Tardive dyskinesia was more prevalent among patients who had spent longer periods of time in psychiatric hospitals (independent of their age). Since this variable appeared to be more important than the length of neuroleptic treatment, it may reflect the effect of regular high-dose neuroleptic administration in hospitals. Similarly, the finding that patients responding poorly to neuroleptics had a higher incidence of tardive dyskinesia might be related to past exposure to high neuroleptic doses. This would indicate that use of neuroleptics at higher than normal dosage should be limited to the most severe cases. However, the dose of neuroleptic currently received by the patient was not found to enter significantly into the regression relationship. This is not unexpected, since high doses of neuroleptics are known to mask tardive dyskinesia.

Previous brain damage tended to be present in the more severe cases of tardive dyskinesia but was not found to be implicated in the appearance of the disorder. The overall incidence of tardive dyskinesia among brain-damaged patients was not higher than among patients with no brain damage. Since the most severe forms of dyskinesia are incapacitating, a history of brain damage would appear to be a relative contraindication to neuroleptic treatment. In the same way, male patients also appeared to be more susceptible to severe forms of the disorder. Because men are often less responsive to neuroleptics than women, a possible explanation of their increased susceptibility to severe tardive dyskinesia is the use of higher neuroleptic dosage. Other factors, such as ECT, insulin treatment, antiparkinsonian medication at the time of examination (which in the clinic is always adjusted so as not to aggravate the tardive dyskinesia), and history of tricyclic antidepressant treatment were not found to be related to tardive dyskinesia in this population of schizophrenic outpatients.

ADDENDUM

Most patients in this study treated with fluphenazine were receiving fluphenazine enanthate I.M. and were rated for tardive dyskinesia when they came to the clinic for their biweekly injections. Consequently, they were evaluated at a time when their fluphenazine blood levels were at their lowest, and dyskinetic movements that are normally masked at higher fluphenazine levels may thus have been exposed. This may have been responsible for the higher incidence of tardive dyskinesia we found among patients treated with fluphenzine.

Hypnotic Treatment of Smoking: The Single-Treatment Method Revisited

BY BERNARD BERKOWITZ, M.D., ANITA ROSS-TOWNSEND, PH.D., AND ROBERT KOHBERGER, PH.D.

The authors replicated Spiegel's single-treatment method by treating 40 self-referred patients in a one-hour hypnosis session for smoking. Their results, a 6-month total abstinence rate of about 25%, were comparable with Spiegel's experience. They recommend future studies that include nontreatment control groups to validate the effects of the hypnotic treatment method of smoking.

JOHNSTON AND DONOGHUE (1), in a 1971 review of the literature on hypnosis in the treatment of smoking, noted the difficulties involved in replicating results: "The hypnosis-smoking literature . . . is primarily anecdotal and rarely in the form of a controlled investigation. . . . Most articles claim many successes and, although they admit to some failures, it is never entirely clear who fails, and when, and why failures occur" (1). They concluded that "Most authors claim success, but their procedures cannot be reproduced." A review of reports since that time shows this still to be true, with the exception of the work of Spiegel (2, 3). His reports of a single-treatment method not only describe in detail the method used but also analyze the results of a 6-month follow-up with 615 patients. Our paper is an effort to address the deficiencies noted by Johnston and Donoghue by replicating Spiegel's method.

Received Sept. 6, 1977; accepted Nov. 14, 1977.

Dr. Berkowitz is Associate Professor of Psychiatry, Dr. Ross-Townsend is Associate Professor of Psychiatry, and Dr. Kohberger is Instructor, Division of Computer Science, Albany Medical College, Albany, N.Y. 12208.

TREATMENT

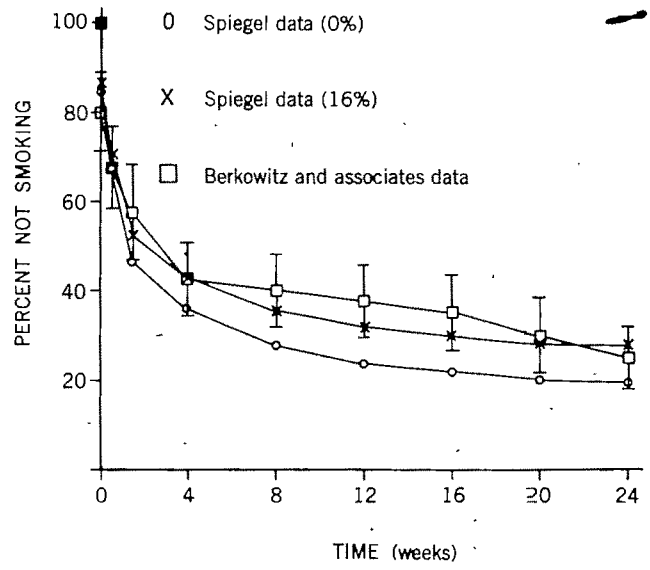
Spiegel has stated that his earlier, open-ended approach to treatment encouraged the patient to delay confrontation with the decision to terminate smoking (3). He thought that if the procedure were going to work, it would do so right away, so he moved to the single-treatment approach. Briefly, Spiegel's single-treatment method consists of taking a brief clinical and smoking history, the application of his Hypnotic Induction Profile, and the induction of trance and confrontation with three basic points: 1) for your body smoking is a poison; 2) you need your body to live; and 3) you owe your body this respect and protection. Three points are taught to the patient so that he can use them as a self-hypnotic exercise 10 times daily. Positively oriented suggestions are given by the therapist, who emphasizes the individual's own responsibility for his success. The method is described in detail elsewhere (2, 3).

0002-953X/79/01/0083/03/$00.40 © 1979 American Psychiatric Association

The treatment was applied in a private psychiatric setting to 40 consecutive patients who came voluntarily after calling for an appointment. Patients were generally referred by word of mouth, although a few were referred by their physicians. There were 20 men and 20 women ranging in age from 22 to 63 years of age (mean=39) who had been smoking for from 5 to 40 years (mean=23). We followed Spiegel's method as faithfully as possible. One of us (B.B.) had seen Spiegel demonstrate the method, had been treated for smoking by this method by Spiegel, and had read Spiegel's procedural descriptions. This investigator did all of the actual treatment.

Although the patients were generally seen only once, we encouraged patients to return for subsequent visits without charge should they fail (a departure from Spiegel's method). Seven patients took advantage of this offer, but none succeeded in terminating smoking.

A research assistant unknown to the patients interviewed them by telephone an average of 64.5 weeks after treatment (range=13 to 104 weeks). This included at least 38 weeks for successes and 13 weeks for failures. We obtained information on outcome and the smoking-free interval (time of complete abstinence) for all patients. Generally, patients could recall dates of failure with good precision, but we calculated the midpoint of the interval based on 4 weeks per month for those patients who gave vague answers. Successful outcome was defined as total abstinence from smoking from the point of treatment until follow-up. Failure was defined as any resumption in smoking from the point of treatment to the point of follow-up; decrease in base-rate smoking short of abstinence was counted as failure.



DATA ANALYSIS

The percentage of patients not smoking at various times and its associated standard error was estimated by the method of Cutler and Ederer (4). In order to compare our data with Spiegel's, calculations were made only to 24 weeks. Two methods were used to estimate the number of follow-up nonrespondents in Spiegel's data who are not smoking. Spiegel's approach was to assume that all nonrespondents have resumed smoking. This will only give a lower bound to the percentage not smoking because it is likely that some of the nonrespondents are not smoking. Kanzler and associates (5) in a follow-up study of a smoking treatment found that 75% of those responding to a mail questionnaire were not smoking while 27% of nonrespondents were not smoking when they were later contacted by telephone. This suggests that the nonsmoking percentage of nonrespondents to a mail questionnaire is about 1/3 of the nonsmoking percentage of respondents. Applying this estimate to Spiegel's data yields an estimate of 16% for the nonrespondents. Standard errors were not calculated for Spiegel's data because estimates were used.

TABLE 1
Comparison of Results of Treatment Outcomes

	Spiegel (N=615)		Berkowitz and Associates (N=40)	
Subjects' Response	N	%	N	%
Stopped smoking (6 months or longer)	121	19.7	10	25.0
Resumed smoking (failures)				
Immediately	29	19.3	8	26.7
Less than 1 week	32	21.3	5	16.7
1 to 2 weeks	39	26.0	4	13.3
2 to 6 weeks	19	12.7	6	20.0
6 to 10 weeks	16	10.7	1	3.3
10 to 14 weeks	8	5.3	1	3.3
14 to 18 weeks	3	2.0	1	3.3
18 to 22 weeks	3	2.0	2	6 7
22 to 26 weeks	1	.7	2	6.7
No response to follow-up	344	55.9	0	0
Failures plus nonrespondents	494	80.3	30	75.0

FIGURE 1
Success Curves for Berkowitz and Associates Data and Spiegel's Data

RESULTS

Table 1 presents Spiegel's data (2) and our data. The shapes of the success curves (figure 1) for our data and Spiegel's data closely resemble each other. Spiegel's data with the assumption that 16% of the nonrespondents were not smoking fall within 1 standard deviation of every point of the sample curve. Spiegel's data with the assumption that 0% of the nonrespondents were not smoking fall within 2 standard deviations of the sample data, and the data for up to 8 weeks and at 24 weeks fall within 1 standard deviation. The 6-month success rate for the sample data, Spiegel (16%), and Spiegel (0%) are 25%, 28.2%, and 19.7%, respectively. These are not statistically different.

DISCUSSION

Various claims have been made for different treatment methods. Our results, although modest at the 6-month interval, reproduce Spiegel's experience and do so over time; as such, they may represent a stable basis for methodologic improvements.

Future studies that include nontreatment control groups are needed to validate the effects of the hypnotic treatment method. Spiegel's single-treatment method can be replicated and meets with a 6-month success rate of complete abstinence of about 25%.

MMPI Diagnosis of Black Psychiatric Patients

BY VICTOR R. ADEBIMPE, M.D., JOSEPH GIGANDET, M.A., AND ELLIOT HARRIS

Black-white differences in MMPI norms may lead to significant misclassification of black psychiatric patients, which can compound diagnostic errors from other sources. The authors suggest that clinicians who use MMPI results in evaluations of black patients interpret test reports carefully, keeping in mind the possibility of spuriously elevated scores and paying careful attention to areas of potential "false positives."

CONTROVERSIES GENERATED by intelligence tests have led to the realization that psychological testing is not always free of cultural bias (1). However, few psychiatrists are fully aware of the possibility that diagnostic errors can result from the use of other types of tests with black patients. The purpose of this article is to bring to the attention of psychiatrists evidence that the Minnesota Multiphasic Personality Inventory (MMPI) may not be entirely suitable for American blacks (2–4) and to suggest ways of dealing with this problem when clinical decisions must be made.

Received July 5, 1977; accepted Nov. 16, 1977.

At the time this work was done, Mr. Harris was a Research Assistant at Western Psychiatric Institute and Clinic.

MMPI COMPARISONS: NORMAL AND PSYCHIATRIC POPULATIONS

In order to determine the MMPI scales in which normal blacks have been reported to score different baselines from their white counterparts, we reviewed the literature on studies comparing high school students, patients in a prenatal clinic, and nonpatient adults (5–11). As shown in table 1, blacks scored significantly higher on the Validity (F), Schizophrenia (Sc), and Hypomania (Ma) scales. The literature on psychiatric patients was also reviewed (12–15), and table 2 shows that the trends seen in table 1 are also found in this population.

DISCUSSION

Differences in MMPI norms for various ethnic, cultural, and national groups are well-documented (16). In most cases, however, profile patterns that are unique to the group are not associated with erroneous psychiatric diagnoses. American blacks appear to be an exception. For example, the majority of a sample of normal rural blacks were labeled schizophrenic by this instrument (17). This pattern is also found in psychiatric populations. Gynther (2) reported a significant difference in the rates of misdiagnosis, with black patients being inaccurately diagnosed more often than white patients. Sixty-six percent of his black psychotic patients were incorrectly classified compared with

44% of the whites. These findings have been replicated and are essentially unchanged by the use of a variety of interpretive formulas (18).

A number of attempts have been made to explain the differences on the basis of social class. Evidence has been produced to show that black patients do not score differently from white patients if the groups are similar in mean age, years of education, and occupation (3, 4, 14, 19). Such studies are useful in showing the cause of the problem but are less relevant to its effects on a group of patients who are over-represented in the social classes at greatest risk. Whatever the causes of black-white differences in MMPI profiles, their most probable effect in clinical situations is significant misdiagnosis among black psychiatric patients.

In general, MMPI diagnoses correlate rather poorly with psychiatric diagnoses (20). Since the MMPI report usually supplements other data, it would seem that blatant disagreement between such reports and clinical diagnoses should lead diagnosticians to rely more on their clinical judgment when dealing with black patients. Unfortunately, clinical judgment may be just as erroneous as MMPI reports. Simon and as-

sociates (21) found a tendency to overdiagnose schizophrenia and to underdiagnose affective illness in black patients admitted to nine psychiatric hospitals in New York State. Welner and associates (22) have also reported the difficulty of accurate psychiatric diagnosis in blacks. In a study of "undiagnosed" psychiatric patients, systematic data collection and discussion of each case by two experienced clinicians still resulted in a significantly higher rate of diagnostic error in black patients.

It is likely, therefore, that uncritical acceptance of MMPI reports on blacks may result in the "confirmation" of one set of errors by another. This situation may be related to the consistently higher rates of schizophrenia reported for hospitalized blacks (23–25).

Clearly, the MMPI should be used with caution in the diagnosis of psychiatric illness in black Americans. Clinical psychologists should attempt to make interpretations that take into consideration the possibility of spuriously elevated scales. There should be a greater awareness of this problem among psychiatrists, so that reports suggesting psychopathology in "false positive" areas will be given closer scrutiny, especially when they are at variance with other clinical information.

When *DSM-III* comes into use, it may be safest to use the MMPI as little as possible for diagnostic evaluations in blacks. However, it remains to be shown that the new manual is free of the potential for diagnostic errors based on cultural differences.

Even if the MMPI is used less often in psychiatric evaluations, it will probably continue to be used for personality assessment in nonmedical settings. Therefore, further study of ways to minimize interpretive errors in blacks appears essential.

Behavior Therapy as a Test of Psychoanalytic Theory

BY R. JULIAN HAFNER, M.D., M.PHIL.

The author describes 4 patients in whom radically new symptoms appeared after intensive behavior therapy. He suggests that fresh symptoms are most likely to develop in a small minority of patients who are unable to learn more adaptive psychological defense mechanisms during or after behavior therapy and that psychoanalytic theory may help predict the nature of such symptoms.

IN A SYSTEMATIC and comprehensive review of attempts to test psychoanalytic theory by experimentation, Eysenck and Wilson (1) found justification for Eysenck's earlier statement that "there is no evidence at all for psychoanalytic theory" (2). They added, "The fact that Freudian theory explains everything is its greatest weakness, because at the same time it predicts nothing."

An important aspect of Eysenck's sustained attack on psychoanalytic theory is his claim that fresh symptom emergence or "symptom substitution" is rarely if ever a consequence of behavioral treatments based on learning theory (3). Behavior therapists appear to unanimously agree with this (4–7).

Therapists who use or systematically observe the use of behavioral techniques while retaining an eclectic approach to psychotherapy have found otherwise (8, 9). Crisp (8) advocated behavior therapy as a means of testing psychodynamic theory but found a major practical problem—the inability of psychodynamically oriented psychiatrists to agree on their predictions of the outcome of behavior therapy in specific cases. I kept Crisp's suggestion in mind during my involvement in the behavioral treatment of 83 patients, 67 of whom suffered from agoraphobia, 11 from chronic obsessional neuroses, and 5 from specific phobias. The basic methods used in the treatment of the agoraphobics are detailed elsewhere (10), and the remaining patients were treated with the techniques of exposure in vivo and response prevention outlined by Marks (11). Of these 83 patients, the following 4 changed their behavior in an unexpected and substantial way soon after treatment.

Received April 4, 1977; accepted July 11, 1977.

At the time this paper was written, Dr. Hafner was Senior Lecturer, Department of Psychiatry, St. George's Hospital Medical School, University of London, London, England; he is now Senior Lecturer, Department of Psychiatry, Flinders Medical Center, Bedford Park, South Australia 5042.

The author wishes to thank Dr. L.K.G. Hsu, who treated the patient described in case 4.

CASE REPORTS

Case 1. Ms. A, a widow of 50 with a 25-year-old son, described the sudden onset of her symptoms. She was in a crowded store 1 year after her husband's accidental death by drowning (some 9 years before her referral): "I was looking at cardigans when my vision started to get a bit hazy and everything started going round. I felt faint and hot, my heart pounded, I hung on to the counter and said, 'I'm not going to let myself go, I don't want to black out.' " She managed to make her way home unaided but subsequently found that similar unpleasant sensations stopped her from leaving home alone, although she could travel up to 400 yards when accompanied. Numerous and repeated medical investigations over 2 years revealed no physical illness, and she failed to respond to a range of psychiatric treatments. Throughout the 8 years of her agoraphobia she remained socially isolated, seeing very little of her elderly parents or son, whom she was unable to visit and who appeared to avoid her, mainly because of her constant complaints about her health. She relied for social contact and support on a succession of mental health workers, on whom she invariably and rapidly became extremely dependent.

She responded to 16 hours (spread over 3 weeks) of graduated real life exposure to traveling outside her home. Particular attention was paid to her fears of falling or blacking out, which she largely overcame. However, as the postural problems receded, she developed nausea, occasional vomiting, and other gastric symptoms that threatened to halt her progress. Nonetheless, after treatment she was able to travel alone on buses and trains for the first time in 8 years. The death of her cat about 4 months after treatment caused her profound distress and was associated with a marked increase in vomiting. This stopped her going out, since she found that she would almost invariably vomit within 100 yards of her home. She then embarked on a series of medical investigations for her vomiting, all of which proved negative. A year after treatment, she was more housebound than she had been before treatment, but vomiting and fear of vomiting had almost totally replaced the postural symptoms as reasons for her inability to venture outside her home alone.

Case 2. Ms. B, a 48-year-old married woman with 3 adolescent children, had suffered for 12 years from a profound fear of dogs and obsessive-compulsive symptoms related to the need to maintain excessive cleanliness of herself and her surroundings. Her mother and sister also displayed severe obsessional symptoms, although neither had received formal psychiatric treatment. Her therapy included 1) graded exposure in vivo to situations where she was likely to encoun-

0002-953X/79/01/0088/03/$00.40 © 1979 American Psychiatric Association

ter dogs and 2) marital therapy aimed mainly at improving the couple's sexual relationship, which had been virtually nonexistent for 4 years. Her total failure to respond, and the failure of a range of psychiatric treatments over the previous 4 years, led to her having a stereotaxic limbic leucotomy after 10 weeks. Subsequently, her fear of dogs was reduced enough for her to agree to a program of graduated exposure in vivo to a dog in the same room, with prevention of her washing and decontamination rituals. The marital therapy continued. After 3 sessions with a dog she was able (with her left hand) to touch it—the first time this had occurred for 12 years—but within 3 hours she developed a paralysis of her left arm, the nature of which was incompatible with any neurological deficit and therefore assumed to be hysterical. She was unable to move her left arm for 10 days and normal function did not fully return for 5 weeks. During the period of her partial paralysis, her fear of dogs virtually disappeared but returned in attenuated form on her recovery. The paralysis temporarily stopped the sexual aspect of marital therapy, which had been progressing very slowly and with great difficulty for both partners.

Case 3. Ms. C, a 44-year-old woman, married for 24 years and with a 21-year-old son, had been severely agoraphobic for 7 years prior to referral. She was virtually unable to leave her home unaccompanied because of weakness and trembling in her legs and fears that she would fall or faint and make a public spectacle of herself. After 15 hours of intensive real life exposure with a group of agoraphobics, she was able to travel alone to a local town and felt more confident socially than she had for many years. Three weeks after treatment, her husband deserted her without warning and went to live with a much younger woman who apparently closely resembled his mother at the same age. After the initial shock, Ms. C appeared to adjust to the situation, but within 6 weeks of being deserted she developed a florid psychosis, with delusions such as "my lungs have collapsed, my body is dead, I have bacteria all over me and my home, I smell all over. . . ." On admission to the hospital she kept exposing her breasts and genital area in order to demonstrate the bacteria. She said, "I have taken all the oxygen from the house; I can't walk out of the house because my lungs are gone. My husband is a murderer . . . all the bacteria have gone to my son's brain." Later she became convinced she was dying of lung cancer and/or stomach gangrene. She remained seriously disturbed for 7 months and was then discharged. Shortly thereafter she was readmitted to a surgical ward for treatment of bilateral calcaneal fractures sustained when she jumped from a first floor window of her home "to escape the smell of gangrene." She returned home 3 months later free of delusions and recovered from her injuries.

Case 4. Mr. D, a 24-year-old bachelor, was referred for therapy when he fainted at a party after hearing an account of a friend's minor operation. He had had a severe needle phobia since he was 8, when he fainted after an antitetanus injection. Subsequently he had been unable to go to the dentist, to discuss needles and hospitals, or to watch TV programs concerning such matters. His father and 3 older brothers also had phobias of needles, knives, and dentists, and the brother who had sought treatment had subsequently become massively obese.

Mr. D was given 5 hours of graded exposure in vivo to needles and medical equipment and environments, culminating in his own venipuncture. He then declared himself virtually free of his fears and within 6 weeks visited the dentist for the first time in 16 years, remaining fairly calm throughout his appointment.

Within days after treatment he began to experience panic attacks and dizziness before leaving home, abnormal anxiety in many social situations, and a fear of public transport, which he avoided if possible. On days when a train journey was unavoidable, he experienced distressing diarrhea and a fear of losing bowel control. Four months after treatment, his fears of public transportation were still troublesome, but tranquilizers helped him to cope. His fear of needles and hospitals had not returned.

DISCUSSION

Blanchard and Hersen (12) suggested that symptom substitution or return following behavior therapy is likely to occur only when the patient lacks the social or interpersonal skills to cope without the secondary gain derived from the symptoms. It seems important to distinguish between the precise nature of new symptoms and the use to which they are put: it is difficult to see how new or previous learning can account for the fairly sudden appearance of radically different symptoms after treatment, but it may well explain how the symptoms are handled by the patient and in particular the way they are used to try to influence others.

If learning cannot readily account for the precise nature of the new symptoms in these 4 cases, can psychoanalytic theory? Central themes in psychoanalytic explanations of phobic behavior (13) are the repression of threatening impulses or feelings and their displacement onto an external object, which then becomes fear-provoking and is avoided if possible. Interpersonal theorists (13) emphasize the unconscious need of the phobic person to be protected by their counter-phobic companion from acting on forbidden impulses.

In case 2, touching the dog may have reduced the patient's capacity to displace forbidden or unacceptable impulses onto it, placing a greater emphasis on the defense mechanism of repression. Some of the "badness" contained symbolically within the dog may have been felt by the patient to enter the left hand, leading her to attempt to somehow dissociate the hand from the rest of her body. Paralysis of the left hand and arm had the additional (secondary) gain of temporarily stopping the highly challenging sex therapy. These three relatively separate factors may have combined to generate the hysterical paralysis.

In case 3, the loss of the patient's counter-phobic companion of 24 years (her husband) may have left her feeling unable to control or contain her unacceptable aggressive and sexual feelings and impulses. Only through psychotic mechanisms could these impulses be both endured and expressed, e.g., her sexual acting-out—ostensibly because of the bacteria but in reality allowing the overt and grossly inappropriate expression of sexuality.

Case 4 is perhaps most readily explicable in psychoanalytic terms. The original fear of needles and hospi-

tals contained within it the patient's displaced (and denied) aggressive impulses. Removal of the fear left Mr. D having to contain these impulses within himself. His fear of losing control of aggressive impulses was reflected in his sharply increased social anxiety, panic attacks, and fear of loss of bowel control. His brother may have reacted to the same problem after treatment by trying, through massive weight gain, to become substantial enough to contain his aggressive impulses.

Although psychoanalytic theory helps explain aspects of the behavior of 3 of these 4 patients after treatment, can it explain why such phenomena were observed in only 4 out of 83 cases? If the inappropriate use of psychological defense mechanisms underlies phobic behavior, then the successful removal of phobias should merely expose this—unless during and after treatment the patient learns more adaptive and appropriate defenses. I have shown elsewhere (14) that the successful treatment of agoraphobia in married women appears to require changes in the personality structure of both patients and their spouses that reflect a more normal use of defense mechanisms. It may be that the emergence of radically new symptoms after behavior therapy is most likely to occur in that small proportion of patients who are unable to achieve a more appropriate use of defense mechanisms after symptom removal. The precise nature of new symptoms may be importantly determined by the way in which defense mechanisms are employed. Such a view is not necessarily incompatible with the notion that phobic and obsessional symptoms are learned: the inappropriate use of defense mechanisms may be one aspect of such learning. If behavior therapists were more willing to acknowledge that fresh symptom emergence might occur after behavior therapy, they could apply to the phenomenom their powers of objective and systematic observation. It may then appear that psychoanalytic theory is both testable and verifiable and that in the course of such testing a fruitful integration of psychoanalytic and behavioristic concepts occurs.

Emergency Room Patients in Concurrent Therapy: A Neglected Clinical Phenomenon

BY FREDERIC KASS, M.D., TOKSOZ B. KARASU, M.D., AND TIMOTHY WALSH, M.D.

The authors found that more than one-third of emergency room patients were participating in concurrent psychiatric treatment. Exploration of the relationship between patient and therapist proved to be a valuable tool in formulating consultation and in ensuring continuity of care.

THE TRADITIONAL emergency room consultation has included an evaluation of the patient's important social and familial relationships. For patients who are participating in psychiatric treatment, the therapeutic relationship deserves the same careful clinical attention.

We have observed that many patients who visit our psychiatric emergency room are involved in treatment. The psychiatric residents who staff our service have difficulty assessing thoroughly the treatment relationship and offering appropriate consultation. Our impression is that residents tend either to deny difficulties which may exist in the treatment or to participate with the patient in an unproductive blaming of the patient's therapist. The literature, including a recent comprehensive review, has not addressed this phenomenon (1).

The present study was designed to determine the percentage of emergency room patients who are already involved in psychiatric treatment and to develop a rationale for consultation.

METHOD

This study was conducted in the psychiatric emergency room of the Bronx Municipal Hospital Center, Albert Einstein College of Medicine, which has been described previously (2). We interviewed 100 consecutive patients during random tours of emergency room service. In addition to the routine psychiatric evaluation, patients were asked questions designed to elicit information about concurrent therapy, expectations from treatment, and feelings toward therapists.

Patients were considered to be involved in concurrent psychiatric treatment if they had regular appointments with a therapist whom they had seen within the previous 6 weeks. High-frequency therapy was defined as one or more sessions a week and low-frequency treatment as less than one session a week. Patients who were participating in intake evaluation or had been seeing a new therapist for less than one month were categorized as beginning treatment.

RESULTS

Of 100 patients interviewed, 36 were found to be in concurrent psychiatric treatment. There were no significant differences in age, sex, or diagnostic distribution between patients in treatment and those not in treatment.

Patients in High-Frequency Therapy

The largest subgroup of emergency room patients in concurrent treatment (N=18) was involved in high-frequency therapy. These patients described their treatment as psychotherapy, with a main focus on discussion and understanding of their problems. There was evidence that many of these patients had strong feelings toward their therapists.

In the following case, the therapist's countertransference may have been a factor in the failure to deal with the patient's strong negative feelings.

Case vignette. A 22-year-old woman came to the emergency room after cutting her wrist. Subsequent to a hospitalization 5 months earlier, she had attended twice-weekly sessions with a psychiatric resident. The patient criticized her therapist, particularly for forgetting a recent appointment. In this context, she stated that her suicidal gesture was proof of the therapist's inadequacy. When contacted by telephone, the resident stated in a pejorative tone, "She is a very sick girl, clearly a schizophrenic, and the wrist cutting is a manipulation." Although he seemed unaware of his frustration and

Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont., Canada, May 2-6, 1977. Received June 1, 1976; revised Aug. 7, 1978; accepted Aug. 29, 1978.

When this work was done, the authors were with the Department of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y. Dr. Kass is now Chief of Psychiatry, Vanderbilt Clinic, Presbyterian Hospital, and Assistant Professor of Clinical Psychiatry, Columbia University College of Physicians and Surgeons, 622 West 168th St., New York, N.Y. 10032. Dr. Karasu is Director, Department of Psychiatry, Bronx Municipal Hospital Center; he is also Associate Professor of Psychiatry and Vice-Chairman, Department of Psychiatry, Albert Einstein College of Medicine, where Dr. Walsh is Instructor in Psychiatry.

annoyance, the therapist's behavior and manner indicated considerable anger and unresolved countertransference.

Patients in Low-Frequency Treatment

Patients in low-frequency treatment (N=9) were chronic schizophrenics who usually came to the emergency room because of problems related to medication. The condition of several patients was deteriorating, apparently because their therapists had confused akinesia with depression or akathisia with anxiety. Recently, several authors have pointed out the high frequency of undetected side effects in patients who are taking psychotropic drugs (3, 4), and Van Putten (5) has suggested that these side effects are a major cause of drug noncompliance. Most of these patients described a withdrawn and socially isolated existence. They may have selected low-frequency treatment to minimize personal contact and prevent activation of conflicts over closeness. In this context, the patient's visit to the emergency room allowed him or her to solve problems without making special requests of the therapist.

Patients Beginning Treatment

Patients who were beginning treatment (N=9) usually acknowledged difficulty in communicating needs to their new therapists. Such patients came to the emergency room in a search for care and attention, often expressed symptomatically in the form of self-destructive behavior. Interviews with the therapists suggested that they may have been uncomfortable with the urgency of the patients' needs. Lazare (6) has noted that some therapists fail to empathize with new patients because of their own difficulty in experiencing the magnitude of the patients' problems (6).

COMMENT

We recommend that the standard emergency room interview include questions about the existence of concurrent treatment, the nature of that treatment, and the patient's current feelings toward his therapist. Direct questioning is indicated because patients may be initially reluctant to discuss treatment and frequently are unaware of significant transference feelings.

Because each case is unique, it is impossible to recommend a single approach to emergency consultation. A patient's visit to the emergency room during a psychotherapeutic crisis may represent acting out of the transference in an effort to alleviate painful feelings. In these cases emergency consultation can be initiated with the patient—contacting the therapist immediately could perpetuate the patient's defenses against autonomous initiation of communication within treatment. The patient's feelings about the therapist can be explored in a nonjudgmental manner. The conflicts underlying the patient's inability to express feelings in the sessions can also be identified.

When the patient has suicidal impulses and there is evidence of a therapist's negative countertransference (as in the case vignette) the therapist should be contacted. Failure to address the therapeutic impasse may foster the continuation of self-destructive impulses and behavior.

In cases where the concurrent treatment more approximates therapeutic management than psychotherapy, an attempt can be made to contact all individuals in the patient's milieu, including the therapist, and to gather information in order to make appropriate recommendations. For example, when the patient is experiencing medication side effects, these can be made known to the therapist. In our experience patients' therapists appreciated our suggestions and found the exchange of information valuable.

In conclusion, more attention to emergency room patients' involvement in concurrent treatment will contribute significantly to the well-being of these individuals and ensure an effective continuity of care. Further research in this area is indicated, particularly with regard to possible negative effects of treatment. Investigation of patients in concurrent treatment will provide a unique window[1] into the psychotherapeutic process.

The Fiscal Crisis in New York City: Effects on the Mental Health Care of Minority Populations

BY PEDRO RUIZ, M.D.

The author describes the effect that severe budget cuts accompanied by guidelines stipulating that direct services be given priority over primary preventive services had on a community mental health center in New York City. He focuses his discussion on the effect these guidelines had on the mental health care services provided the minority populations served by the center. Before the budget cuts, 1 out of every 4 staff members was a nonprofessional indigenous worker. After the cutback, 2 out of every 3 of the people laid off were nonprofessionals. The author provides a number of recommendations to help government agencies plan budget reductions without sacrificing primary prevention efforts.

IN THE CURRENT DECADE the United States has gone through the worst urban crisis ever experienced by any country in the Western hemisphere. The promises of the "melting pot" that most large cities represented to different migrant groups no longer exist. Among the factors that contributed to the rise in urban populations are the following: the black rural migration to the large cities, the attraction that prospering industries offered the unskilled worker, the social advantages obtained by large labor movements in big cities, and the socioeconomic support extended to the poor and disadvantaged in urban areas. However, accompanying these developments were substandard and insufficient housing, a rise in the incidence of crime and delinquency, a weakening of the educational system, mass transit problems, difficulties in communication systems, mass unemployment, and deterioration of health care. In this paper I would like to focus on the impact that the fiscal crisis of New York City had on the mental health care systems for minority populations living in this metropolis.

As is well known, health costs have escalated during the last few years to such proportions that illness can represent a financial catastrophe for any family. Modern technical developments, high labor costs, expensive medical and paramedical training, and increases in malpractice insurance costs have contributed to this situation. Although we have been reading and hearing much about government debates regarding a national health insurance system, it is still far from being a reality.

In 1975 and 1976 the City of New York regrettably achieved notoriety as the prototype of a city in crisis with the emergence of serious financial insolvency. Among other services the city's health care delivery system was profoundly affected by severe budget cuts. I would like to analyze what I consider to be a disaster in health services by depicting the impact of the financial crisis on a large comprehensive mental health center located in a deprived ghetto area of New York City—the Southeast Bronx.

THE PROGRAM

In the 1960s community psychiatry ascended to the center of interest for American psychiatry (1). The emphasis on community psychiatry led to the development of many innovative approaches to the treatment of the mentally ill. In 1963 the federal government launched its "bold new approach," and Congress passed the Community Mental Health Centers Act setting specific guidelines for the operation of mental health centers. As a result of this piece of federal legislation, the Albert Einstein College of Medicine obtained a grant for the operation of the Lincoln Community Mental Health Center, a comprehensive mental health center in the southeast area of the Borough of the Bronx in New York City.

Since its inception in 1965, the Lincoln CMHC has been a vivid example of the prevailing social model in the delivery of human services emanating from the socially oriented movements that were a part of the "War on Poverty" (2). As a result of this, one of the center's major emphases was on the primary prevention of mental illness. The emphasis on primary prevention had already been emerging in the last decade in a number of different settings ranging from solo to group practices and including neighborhood health centers and teaching hospitals (3). In another framework, public health professionals were simultaneously stressing the provision of mental health services as a coordinated part of primary health care (4). The emphasis on primary prevention went hand in hand with the attempt to provide secondary and tertiary pre-

vention programs as part of the armamentarium of service delivery. Along these lines, a major innovative feature in the service delivery of the Lincoln CMHC was using culturally sensitized and community-related paraprofessional staff. This kind of staff use has been given much recognition in the general medical literature (5) as well as in psychiatric literature. In developing outreach programs in consultation, education, self-help, and community action, the center attempted basically to foster the development of a more competent community (6).

NEW YORK CITY'S FINANCIAL CRISIS

Starting in the spring of 1975 the Lincoln CMHC was confronted with serious budget reductions as part of the local government's attempt to deal with its fiscal situation. Thus, with little warning and without opportunity to plan, the center was notified in June 1975 of a budget reduction of approximately $750,000 from an annual budget of close to $4 million. This budget cut had to become effective within one month—on July 1, 1975. In June 1976 another reduction of about $500,000 was implemented, thus reducing the center's annual budget to approximately $2.6 million by July 1, 1976. These two large budget cuts within a period of one year were accompanied by guidelines from the New York City Department of Mental Health and Mental Retardation. These guidelines gave priority to direct patient care, thus protecting "collectible" services covered by such third-party insurers as Medicaid and Medicare. These actions taken by the local government not only forced the reduction and elimination of essential services geared toward primary prevention (e.g., the consultation services to community agencies and community organization services) but also protected hospital-based programs throughout the city at the expense of community-based programs in poverty areas.

It is well known that hospital-based providers are more capable of maximizing third-party collections. This circumstance might well account for the fact that the Medicare and Medicaid systems in the city have become very expensive operations. An average New York City welfare family of four receives $4,500 annually for all living expenses other than medical expenses. The same family costs the city $9,000 a year in medical services (7). It should be noted that the guidelines regarding service priorities were put into effect without local community input. These guidelines were based exclusively on the opinion prevailing in the city's mental health bureaucracy.

DISCUSSION

Since the inception of the Lincoln CMHC, every effort was made by its administration to plan the staffing patterns as well as staff recruitment and selection in such a way that the program's overall philosophy and goals of primary prevention would be enhanced and a social model of service delivery would be emphasized. Table 1 shows the center's staff breakdown before the budget reductions and consequent layoffs. With full staffing, all community-oriented program goals were easily met. The percentages shown in table 1 are comparable to the population percentages in the catchment area served by the program, which according to the 1970 census report were 57% Hispanic, 33% black, 7% white, and 3% other.

Table 1 also shows that 1 out of every 4 staff members was a nonprofessional indigenous worker. These staff members represented a natural tie with local community groups and agencies because they were recruited primarily from the neighborhood itself and thus brought relevant sociocultural characteristics to the services offered. They also facilitated client identification with the program because these workers were predominantly black and Puerto Rican. It is also worth noting in table 1 that 27% of the professionals in the program were of minority background, thus reinforcing the community-geared and social model character of the program.

Table 2 shows the positions eliminated as a result of the budget cuts during the period from July 1, 1975, to July 1, 1976. It can be seen in this table that 2 out of every 3 individuals laid off were nonprofessionals. As a result of the priority guidelines put forth by the local government bureaucracy, the impact on minority employees terminated from the program was tremendous. There were unforeseen repercussions on the socioeconomic life of this disadvantaged neighborhood.

As a result of the budget cuts the center's administration had to reduce and subsequently to close its active consultation-education department, which employed 3 professionals and 12 nonprofessionals. The consultee community organizations left to fend for themselves included churches, settlement houses, youth and senior citizen's service organizations, and two elementary schools. The city bureaucracy's guidelines accordingly succeeded in effecting the elimination of all of the center's primary prevention activities while they protected direct services. In fact, there was a 15% increase in the individual and group therapy sessions, which were conducted for the most part by professionals.

It is my belief that the program goals, which were imposed on the center, will undoubtedly lead in the near future to an increase in the number of patients institutionalized. A financial saving for the city will thus bring damage to the patients, their families, and their hopes for reintegration into society. Once again, a severe blow has been administered to an impoverished minority community. In short, the city's approach in dealing with the fiscal crisis was to produce an immediate increase in revenue to alleviate its financial crisis. The result may be a frightful situation in terms of patient care, which will undoubtedly lead to an intensification of the fiscal crisis in the long run.

RECOMMENDATIONS

In my opinion, New York should have pursued different and less destructive approaches to deal with its financial crisis. These would include the following:

1. Needed expensive services, such as court programs, services for the mentally retarded, addictive services, and adolescent programs, should have been regionalized. Regionalization could have been done on a borough-wide if not city-wide basis, disregarding political considerations and focused on the needs for services in a geographic area. Regionalization would have eliminated unnecessary duplication of services and alleviated the fiscal crisis without curtailing essential programs.

2. Administrative control should have been centralized. This would have helped to reduce overhead and administrative costs. Centralization could also have been done without regard to political considerations, which are still regrettably prevalent in the city bureaucracy. Furthermore, centralization could have been directed toward program effectiveness and could have emphasized the protection of public services, thus benefiting the poor and the needy.

3. Consortium models should have been used for service delivery. This would have protected a larger number of agencies in the network of health care delivery. Undoubtedly, local community groups would have benefited by the use of consortium models. Without such models, large private or quasiprivate corporations will take control of health care services.

4. Planning for services should have been comprehensive, taking into consideration both long- and short-range plans that are intrinsically related rather

than just short-term plans. This would certainly have avoided the introduction of measures that would tend to create financial problems later.

5. The city-wide philosophy and goals for mental health care should have been redefined. One hopes that, as a result, comprehensiveness of services and continuity of care would emerge stronger than they were and would provide special support for primary prevention approaches. To pursue this goal, local and state governments would have had to collaborate in every aspect of mental health care delivery.

6. In addition to each agency's local community board, comprising civic leaders and consumers, some ways of community representation on a borough-wide basis should have been developed. It is well known that local community input, although vocal, inevitably gets lost in the maze of the city's bureaucracy. With government decentralization at a borough-wide level and community input centralized at the same level, perhaps the consumers would have a better opportunity to influence their own destiny.

7. The catchment areas should have been redefined, not according to political structures or to the providers' geographical controls but according to the natural locus of needs for services.

8. Unification of services should have been attempted. There should have been fewer providers delivering more services. These changes need to be backed by appropriate legislation at the federal, state, and local government levels.

9. Monitoring and evaluation of programs should have been done by independent third parties in order to avoid conflicts of interests.

These recommendations are especially important because the fiscal crisis of urban America is here to stay. Furthermore, even without a fiscal crisis, every attempt should be made to maximize program effectiveness and cost control for the benefit of the taxpayers.

CONCLUSIONS

The example of this large urban mental health center was presented in an attempt to demonstrate the impact that the New York City fiscal crisis had upon the mental health care delivery system, particularly on minority populations. I feel that the experience of the Lincoln CMHC is a good example of the way the city's mental health bureaucracy dealt with its fiscal problems. I hope that my observations will help government agencies in planning budget reductions while avoiding catastrophic consequences on the primary prevention aspects of health care. Politically, it is probably easier to sacrifice urban groups because they are composed of minorities, mostly blacks and Hispanics. Americans often blame societal problems on the big cities, forgetting that progress and the great strides in health care have also come from them. Urban communities like the Southeast Bronx represent not only a local crisis but also a national promise.

Mood and Affect: A Semantic Confusion

BY HOWARD OWENS, M.D., AND JERROLD S. MAXMEN, M.D.

Although semantic clarity is a cornerstone of scientific psychiatry, psychiatrists often use technical words with the false assumption that their meanings are clear. The common use of the terms "mood" and "affect" illustrates this point. The authors attempt to show how unclear definitions of these words have led to confusion and how they could be more clearly understood by careful semantic and phenomenologic analysis.

> The merely descriptive literature of the emotions is one of the most tedious parts of psychology. And not only is it tedious, but you feel that its subdivisions are to a great extent either fictitious or unimportant, and that its pretences to accuracy are a sham.
>
> —William James (1)

A REVIEW of psychiatric texts and dictionaries reveals wide variations and contradictions in the definitions and uses of the terms "mood" and "affect." There are two common but unrelated ways of distinguishing the terms. Some writers emphasize the duration of an emotional state, regarding affect as a person's immediate condition and mood as a prolonged state or summation of numerous instances of affect (2–5). For example, Linn stated that "when an affective state is sustained for a considerable period, one speaks of a mood" (3, p. 808). However, does an affect need to exist for seconds, hours, days, or weeks before it evolves into a mood? Moreover, saying that affect and mood are transitory and persistent states, respectively, conflicts with popular usage. It is not uncommon to remark, "Right now, I'm in an angry mood."

The other approach depends on a distinction between subjective and objective emotional phenomena. Kolb (4) defined affect as "subjectively experienced." By contrast, other psychiatrists emphasize the subjective nature of mood and regard affect as, by definition, observable. For example, Hinsie and Campbell (6) stated that mood is "experienced internally," while affect refers to "external manifestations of the subject's feeling." English and English (7) likewise regard mood as "internal" and define affect as "a feeling state . . . accompanied by noticeable bodily activity." The latter definitions reflect the commonly held opinion that affect refers to observed reactions and mood pertains to verbal reports about one's "inner" state. However, in actual practice, clinicians sometimes conclude entirely by observation that a patient's mood is depressed (e.g., from the patient's knitted brow, slow movements, glum facies, sighs, etc.).

Another illustration of how psychiatric usage often fails to follow any of these standard distinctions is provided in Rapaport's description of practitioners' habitual use of the word affect to refer to phenomena that are both subjective and objective, temporary and sustained:

> We call affect not only the infant's rage . . . and the adult's anger accompanied by the corresponding expressive movements and other physiological concomitants, but also the subjective feelings of those well-controlled adults who show little or no affect expression, as well as the anger of over-controlling compulsive persons who just "know" that they "could be" or "should be" angry . . . And we must take notice of such affects as anxiety, guilt, elation, depression, which—in contrast to the momentary affects so far mentioned—may take pathological chronic forms; even more important, they may take characterological chronic forms, as in anxious people, gay people, gloomy people, bashful people, etc. (8, p. 478)

TWO ALTERNATIVE APPROACHES

Plutchik (9) maintained that because descriptions of the subjective aspects of feeling states lack reliability, they cannot provide a general basis for a theory of emotion. Instead, his theory of feeling states stresses their adaptive functions and the relationships among different types of emotions in terms of their intensity, similarity, and polarity. Although his ideas are useful in conceptualizing emotions from an adaptive perspective, they fail to clarify more fundamental problems, such as the meanings of and distinctions between mood and affect.

In order to address these issues, Ketai (5) reclassi-

fied mood and affect into seven subcategories. His definitions primarily emphasize temporal distinctions: affect means an "immediate emotional experience," and mood constitutes a feeling state lasting over a "specified period of time." He also suggested that affects have greater intensity and flexibility than moods. Further, he considers both mood and affect to have subjective and objective components; "affective sensation" refers to a patient's subjective reports, while "affective display" means the overt behaviors associated with an emotion. He emphasized the need to describe the qualities of affects, such as their range (variability), intensity (strength or depth), and appropriateness (to current situations and contents of speech). Although Ketai's classification system clarifies certain issues, it tends to rehash previously cited definitions. More importantly, it avoids fundamental semantic and phenomenologic issues that must be addressed if one seeks a fuller understanding of the terms mood and affect.

TOWARD SEMANTIC CLARITY

Hayakawa (10) pointed out that defining words by other words at the same level of abstraction (e.g., saying that affect is an emotional experience) leads nowhere; the best definitions are those which are referable to lower levels of abstraction, i.e., closer to concrete phenomena. The problem with most traditional psychiatric distinctions between mood and affect is that they are based on concepts of emotion which are not readily translatable into concrete clinical phenomena.

Psychiatrists have confused the meaning of terms like mood and affect because they have misconstrued the process by which we perceive and describe emotions. Mood and affect have been regarded as concrete, observable phenomena, when in fact both terms are abstractions, i.e., they are based on inferences from observable phenomena. In examining a patient the psychiatrist makes observations that can be classified in various ways—physical signs (pallor, tremor), facial expressions (grimaces, smiles), motor activity (fidgeting), verbal statements ("I feel awful"), and other utterances (groans, sighs)—all of which are objective. Based on these observations, the psychiatrist proceeds to make inferences about affect and mood. The process of inference is necessary because affect and mood are not directly observable.

Schafer (11) argues that psychiatrists have reified concepts like affect. With regard to the concept of anger he writes,

> We have the illusion that we are referring to something that may be designated by a concrete noun, that is, to a unit that can be pointed to, like a claw, or a fang, or a fecal mass. But that is not what anger is. The anger of common usage is really an abstract noun; it is a rubric for a set of referents, and it is the referents rather than anger that can be pointed to." (11, pp 424–425)

Thus a psychiatrist can point to physiological events like pallor or tremor or to specific statements that a patient makes, but he cannot observe anger itself. The statement "He shook his fist" reports an observation. If we say, "He was angry," we have already made an inference. If the patient says, "I'm angry," then it is he who has made an inference, which he is reporting. The patient is not observing his own anger directly any more than we are.

The attempt to construe mood and affect as subjective or internal merely conceals a popular misconception. Schafer (11) points out that the mind is not localized in space, and affects cannot be "inside" anything in any sense but a metaphorical one. That an affect can, of course, be private does not mean it must be construed as "internal." Private thoughts are those which are not shared, including those which are unconscious. If a patient's affect is kept private, then clearly no one else knows about it. Any conclusion we reach about a patient's affect is necessarily based on what he has shared or exhibited so that it is no longer private.

Schafer acknowledged a debt to Ryle (12), whose analysis of the mind devoted considerable attention to the concept of mood. Ryle demonstrated that philosophers and psychologists have often conceived of mental operations as chains of cause and effect events analogous to physical causes and effects. According to this view there is supposed to be an internal mental cause, such as mood, which is not directly observable but which produces overt reactions and behavior. In fact, no one's mind operates this way. "When we describe people as exercising qualities of mind," writes Ryle, "we are not referring to occult episodes of which their overt acts and utterances are effects; we are referring to those overt acts and utterances themselves" (p. 25). When a person identifies his own mood, he does so by recognizing concrete bodily feelings (such as fatigue, heaviness, or sighs) and particular thoughts (that he is inept, worthless, stupid). There is no such thing as purely "internal" mood that exists in isolation from such feelings or thoughts. Similarly, we can only tell if another person is depressed by observing whether he acts or sounds depressed; we cannot examine any hidden mental events "behind" his expressions. It was for this reason that James (1) went so far as to identify emotion with the perception of bodily changes: "If we fancy some strong emotion," he wrote, "and then try to abstract from our consciousness of it all the feelings of its bodily symptoms, we find we have nothing left behind. . . . A cold and neutral state of intellectual perception is all that remains" (1, p. 451). A mood does not produce bodily feelings but rather is an inference from them.

Ryle (12) clarified this distinction by pointing out that a mood is nothing more than a disposition to act or react in a certain way. A disposition (such as intelligence or depression) is not an event (such as solving a problem or crying). The relation of a disposition to its exercise in behavior is not causal. A disposition

is not witnessable; only its exercise in specific actions can be witnessed. Recognizing a disposition entails a prediction. If we say that a man is depressed, we are saying that he is likely to speak morosely, perhaps to cry, move sluggishly, etc., and we base this conclusion on some previous patterns of such behavior.

Similarly, in speaking of an unconscious affect that manifests itself neurotically or characterologically, the clinician is making both inferences and predictions. The conclusion that a patient is unconscious of his depression is an inference derived from observations of or interactions with him. Statements about unconscious affect are often erroneously taken to be cause and effect statements. For example, an adolescent girl who runs away from home is described as acting out feelings of depression of which she is unaware. Rather than saying that depression caused her to run away, it would be more precise to frame a prediction about her affect on the basis of her manifest behavior. The clinician might then say that if the patient stops running away, she is likely to feel depressed. Just as a conscious affect may be inferred from sobs and moans, so a potential affect may be inferred from neurotic acting out.

Thus, the difference between mood and affect does not lie in the former being subjective and the latter being objective. Mood and affect can both refer to a person's disposition to react emotionally in certain specific ways. Consequently, to describe a particular mood or affect entails a prediction about how a person will act, based on previous patterns of behavior. Both mood and affect are abstractions, and both are inferred from concrete phenomena. The overlap between the two concepts is considerable. Perhaps the main distinction between them is that inferences about mood stem from present observations and past events (and therefore belong in a patient's history rather than as part of his mental status examination), while inferences about affect usually pertain only to current observations. We have dignified this distinction largely because these two terms are so thoroughly entrenched in our clinical vocabulary.[1] Nevertheless, we would suggest that emotional states could be described quite adequately without resorting to this distinction.

To include mood and affect side by side in a mental status examination amounts to a category mistake because it implies that there are two separate sets of observations. In fact, there is only one set: any observable event or bodily feeling from which the clinician makes an inference about affect could also be incorporated into a conclusion about mood. The converse, however, may not be true. Because statements about mood are usually derived from observations of past as well as present phenomena, all referents to mood do not apply to affect. All observations about current emotional expression can be included in a single category. Whether we call this category "affect" or some other word (e.g., "feeling tone") the important point is to recognize the distinction between observations and inferences when describing emotion.

We believe that there can be greater clarity in reporting a psychiatric case if this distinction is underscored: inferences about emotional states should not be reported without the concrete observations that led to these inferences. Just as a good clinician offers examples that justify the statement that a patient is delusional (e.g., the patient's stated belief, "I'm Jesus Christ"), so should he describe the events (e.g., crying and frowning) that justify his conclusion that a patient is depressed. When such observations do not accompany inferences about emotional states, the reliability of the inference is open to question. Moreover, because the range, duration, appropriateness, and intensity of these phenomena (5, 9) are also observable, statements about these qualities will further enhance the reliability of one's description. The patient himself can be introduced to this way of thinking by reporting specific events and feelings to explain a conclusion. The observations of both clinician and patient can be reported together, and inferences can then be made from the whole body of observations rather than being mixed in with them. Implementing these guidelines will reduce the current semantic confusion about describing emotions.

[1]It was primarily for this reason that, after some debate, the Task Force on Nomenclature and Statistics preferred the term "affective disorders" instead of "mood disorders" for the proposed *DSM-III*. Because we view mood as a disposition persisting over time, and because the Task Force itself defines affective disorders as being "characterized by a primary disturbance of mood" with the term "mood" referring to a "prolonged emotion" (13), it might be more accurate to call this category "mood disorders" in the final version of *DSM-III*.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Noradrenergic Hyperactivity in Opiate Withdrawal Supported by Clonidine Reversal of Opiate Withdrawal

BY MARK S. GOLD, M.D., D. EUGENE REDMOND, JR., M.D., AND HERBERT D. KLEBER, M.D.

The widespread use and abuse of opiates and their unique effects on mood have generated considerable interest and study by diverse health and research scientists. However, the studies and the literature have failed to produce a unifying theory of opiate action on neurotransmitter systems or to lead to new nonopiate medical treatments for opiate withdrawal. We previously hypothesized that the locus coeruleus or other brain regions inhibited by both opiate and alpha-adrenergic receptor stimulation are responsible for opiate withdrawal (1). We proposed this hypothesis after observing that specific behaviors elicited in primates by dangerous situations, locus coeruleus stimulation, and drugs like piperoxane, which activate the locus coeruleus, were strikingly similar to the behaviors and physiologic changes associated with opiate withdrawal. We concluded that locus coeruleus stimulation or piperoxane administration could be useful as a model for the signs and symptoms of opiate withdrawal, so that drugs which block the specific behaviors elicited by these provocative procedures, like clonidine (2, 3), and which inhibit the function of the locus coeruleus may be useful in the medical treatment of opiate withdrawal and naturally occurring anxiety states. Preclinical studies have suggested that the pontine noradrenergic nucleus locus coeruleus is a brain alarm modulator (2–5) which may be essential to the human emotions and behaviors relieved by opiates and evoked in opiate withdrawal (1). These data and our evidence of clonidine's efficacy as an effective nonopiate treatment for opiate withdrawal support the hypothesized noradrenergic hyperactivity as the neurobiological substrate for opiate withdrawal (1).

Dr. Gold is Director of Research and Training, Fair Oaks Hospital, 19 Prospect St., Summit, N.J. 07901, and Vice President for Basic Research, Psychiatric Institutes of America. Dr. Redmond is Associate Professor of Psychiatry, Yale University School of Medicine, where Dr. Kleber is Clinical Professor of Psychiatry. Dr. Kleber is also Director, Substance Abuse Unit, Yale University School of Medicine and the Connecticut Mental Health Center.

Method

We administered 5 μg/kg of clonidine to 6 male opiate addicts after discontinuation of chronic methadone treatment (doses of 15–50 mg/day) and to 6 heroin addicts who exhibited signs and symptoms of opiate withdrawal. The subjects had been addicted to opiates for 2–10 years. Those subjects who were being maintained on methadone had been taking methadone for 6–60 months. All subjects gave informed consent to participate in the study, which required a 2-day phased withdrawal from methadone before admission to the research unit (for the methadone subjects) and at least 36 hours with no opiate administration. All subjects had objective signs of opiate withdrawal and urine specimens that showed residual opiates. Baseline observations for the presence or absence of objective withdrawal signs (e.g., rhinorrhea, lacrimation, increased blood pressure) were made every 30 minutes by a research nurse, beginning at 8 a.m. while the subjects were at bed rest. The 12 subjects were also asked to complete self-rated analogue scales for nervousness and tension. At 11 a.m. and 1 p.m. subjects received placebo or 5 μg/kg of clonidine orally in matching vehicles. All trials were double-blind, with patient, nurse, and physician unaware of the order of administration. All subjects completed the entire 3-hour baseline and two consecutive 2-hour blind trials.

Results

As expected, the number and severity of opiate withdrawal signs and symptoms increased during the baseline period in all 12 patients. In both the heroin withdrawal and methadone withdrawal groups, clonidine administration produced a rapid, prolonged, and significant reduction of opiate withdrawal signs and symptoms. Methadone withdrawal signs were reduced from a mean just before clonidine administration of 13.7±1.2 (SEM) to 0.3±0.3 90 minutes after administration (paired t test, $p<.01$) and heroin withdrawal signs and symptoms decreased from a preclonidine mean of 8.1±1.1 to 0.8±0.6 (paired t test, $p<.01$). All subjects also reported a dramatic relief of subjective distress. Patients who had reported they were "anxious, tense, or felt impending doom or death" denied these feelings at 120 minutes after clonidine administration. Nervousness and tension ratings on self-rating analogue scales were significantly decreased from a pretreatment mean of 54±3 (70 was the highest score) to 25.3±1.5 at 120 minutes. All 12 patients stated before clonidine administration that they were in withdrawal or "kicking" but said they were not kicking 120 minutes after administration. There were no reports of euphoria or "feeling high" after clonidine. Placebo had no significant effects. Five methadone withdrawal patients were offered clonidine alone on discharge and all chose this over a return to methadone. All heroin withdrawal patients were offered clonidine alone to be taken on an outpatient basis for 1 week; again, all chose this option.

All outpatients received 5 μg/kg of clonidine orally b.i.d. for 1 week. Outpatients were rated for abstinence signs daily for the week of outpatient clonidine treatment and for 1 additional week of follow-up. The only consistent complaint in both groups was occasional sluggishness and a sleep continuity disturbance. There were no signs of an exacerbation of opiate withdrawal, and 10 patients were clonidine-free and opiate-free at the 2-week follow-up. All of these patients had made previous unsuccessful attempts to withdraw from opiates. Although it is too early to evaluate the effects of a brief clonidine treatment on permanent abstinence, these data strongly support preliminary evidence for the efficacy of clonidine in the acute treatment of opiate withdrawal and as an alternative detoxification strategy (1).

Discussion

This trial was undertaken with specific hypotheses as to the mechanisms responsible for opiate withdrawal, based on our studies of the major noradrenergic nucleus locus coeruleus (LC). Striking similarities were noted between the effects of electrical or pharmacologic activation of this nucleus and those noted after opiate withdrawal. Both morphine and clonidine blocked the effects of electrical stimulation and pharmacologic activation of the LC in primates (2, 5). Although clonidine and the opiates blocked the effects of electrical stimulation and pharmacologic activation of LC, decreased neuronal activity in the LC, and decreased norepinephrine (NE) release (6–8), clonidine appears to exert its effects through nonopiate alpha-2-adrenergic receptors (6). It also has been recently demonstrated by Simon[1] that clonidine does not have any significant affinity for the opiate receptor. These data suggest that the opiate withdrawal syndrome is due to increased NE neuronal activity in areas such as the LC which are regulated both by alpha-2-adrenergic and opiate receptors. These data also support the notion that clonidine is an effective nonopiate treatment which replaces opiate-induced inhibition by augmenting alpha-2-mediated inhibition of noradrenergic activity. Our findings suggest that changes take place in the sensitivity of the alpha-2 receptors that are thought to regulate neuronal activity of the NE nuclei by powerful recurrent collateral inhibition (6). Since neuronal activity of these NE systems would be chronically inhibited by exogenous opiate administration, these receptors might also become subsensitive to the nonopiate neurotransmitter that normally inhibits their activity. Pharmacologic agents such as clonidine, which specifically inhibit noradrenergic neuronal activity via these alpha-2 receptors, would be expected to ameliorate withdrawal symptoms and possibly normalize receptor sensitivities. Although the exact neural mechanism mediating opiate withdrawal symptomatology remains to be defined, the absence of opiates in the dependent individual could readily result in a loss of opiate inhibition in brain areas like the LC and subsequent large increases in noradrenergic neuronal activity and NE release. Our hypothesis of noradrenergic hyperactivity as the neurobiological substrate mediating opiate withdrawal signs and symptoms can explain the effects of clonidine and the partial effects of other nonopiate medications on opiate withdrawal symptomatology (9, 10) by their inhibitory action on NE function.

This preliminary study supports an augmented noradrenergic system, released from opiate inhibition, mediating opiate withdrawal. It also suggests that clonidine may be a more definitive treatment for opiate withdrawal signs and symptoms produced by the discontinuation of either methadone or heroin than any treatment now available. The data indicate that opiate withdrawal may be a model for naturally occurring anxiety or panic states in man and suggest anxiolytic activity for clonidine.

Endocrine Testing in Tardive Dyskinesias: Preliminary Report

BY ALAN H. ROSENBAUM, M.D., TOSHIHIKO MARUTA, M.D., NAI-SIANG JIANG, PH.D., RAYMOND G. AUGER, M.D., JUAN R. DE LA FUENTE, M.D., AND DRAKE D. DUANE, M.D.

Tardive dyskinesia is a buccal-lingual-masticatory triad associated frequently with abnormal movements of the extremities and occasionally of the trunk. Long-term administration of antipsychotic medication is often implicated as the causative factor, although other medications are also believed to be predisposing and/or causative factors. Some of the dyskinesias are preceded by ECT and brain damage (such as cerebrovascular accident); others seem to occur spontaneously even in the absence of a drug history. The dyskinesias occur more frequently in women and in older patients than in men or younger patients (1-3).

Recently, Davis and associates (4) and Alpert and associates (5) reported a high incidence of affective disorders in patients with tardive dyskinesia. Our data (3) showed that 17 of 18 consecutive patients with tardive dyskinesia had primary affective disorders and that responses of dyskinesia and depression to treatment paralleled each other. These findings led us to hypothesize that primary affective disorders are a major predisposing factor for the development of tardive dyskinesia and that patients with tardive dyskinesia have neuroendocrine abnormalities similar to those of patients with primary affective disorders (6). To test this hypothesis, we measured the levels of 24-hour urinary free cortisol (UFC) and blood thyroid-stimulating hormone (TSH) in consecutive patients with tardive dyskinesia and compared these levels with those found in controls. In patients with primary affective disorders, 24-hour UFC levels were elevated (6) and the response of TSH to thyrotropin-releasing hormone (TRH) stimulation was reduced (7). Further studies have indicated that the high level of glucocorticoids may blunt this response (8); thus, there may be an inverse relationship between the level of corticosteroids and that of TSH.

Method

In 18 consecutive patients with tardive dyskinesia (diagnosed by one psychiatrist and one neurologist) who were not receiving antidepressant medication, the values for 24-hour UFC and blood TSH were determined. Five patients who were tested before August 1977 did not have serum TSH determinations.

TSH levels were determined by a double-antibody radioimmunoassay procedure. TSH standard 68/38 was obtained from the National Institute for Biological Standards and Control, Mill Hill, England; UFC was determined by a method modified from that of Murphy (9) by a double-extraction technique. The standard was obtained from Sigma Chemical Company, St. Louis. The mean level in 100 adult control patients was 66 μg/24 hours, with an upper limit (2 standard deviations above the mean) of 108 μg.

Results

Values for UFC (see table 1) ranged from 81 to 630 μg/24 hours, with a mean of 198 (SD=147). The difference between our study group and the adult control group was statistically significant ($p<.01$, one-tailed Student's t test). Of the 18 patients, 13 (72%) had elevated UFC levels (>108), and 2 (11%) had upper normal levels of UFC. Of these 15 patients, all but 2 (pa-

tients 4 and 6) fulfilled at least four of the depressive symptoms in the Research Diagnostic Criteria (RDC) (10), indicating at least "probable" depression, although only 9 of the 13 (69%) claimed a dysphoric mood. Patient 4 fulfilled the RDC criteria for mania; patients 6, 11, and 13 had delusional ideations. None of these 15 patients met RDC criteria for schizophrenia. However, all of these patients had been receiving some type of antipsychotic medication before the onset of the tardive dyskinesia.

Of the 3 patients with normal UFC levels, 2 (patients 14 and 16) had no drug history before the onset of the tardive dyskinesia. Patient 14 had suffered a cerebrovascular accident before the onset of the dyskinesia and was given haloperidol to control the dyskinesia. The patient denied feelings of depression, but she fulfilled the other RDC criteria for depression with severe withdrawal. Except for some tooth extractions, patient 16 had no significant history before the onset of the tardive dyskinesia. According to RDC, she was depressed. The third patient (patient 1), who was severely depressed and had nihilistic delusions, was receiving antipsychotic medication.

UFC and TSH levels were determined after treatment for depression for 4 patients. Patients 5 and 21 were in remission and had UFC levels of 42 and 52 μg/24 hours and TSH levels of 9.1 and 17.9 μU/ml, respectively. Patients 8 and 12, who were in partial remission, had UFC levels of 99 and 128 and TSH levels of 2.8 and less than 1, respectively.

TSH values tended to be inversely related to the cortisol levels ($p<.12$, Fisher's exact test); in our laboratory, TSH levels of 0–3 are considered to be essentially zero. Most patients with TSH levels greater than 3.0 had UFC levels less than 108.

Discussion

Carroll and associates (6) have reported elevated UFC levels in primary affective disorders but not in schizophrenia. Our present data showed that 13 of the 18 patients (72%) had elevated UFC levels, which supports our hypothesis that the endocrine dysfunction in these patients is similar to that in patients with primary affective disorders. Further, patients with low TSH levels tended to have elevated UFC levels, which suggests an inverse relationship. None of these patients fulfilled RDC for schizophrenia at the time of our evaluation. Instead, all of the patients with elevated UFC levels, except the manic and paranoid patients, fulfilled four to six of the eight RDC depressive symptoms, although many denied a dysphoric mood.

Repeat UFC and TSH determinations further supported our hypothesis. Two patients in remission had normal levels of both UFC and TSH, and 2 patients in partial remission had elevated UFC levels and low TSH levels.

Although our study is a preliminary one, the findings indicate that a subgroup of patients with tardive dyskinesia have endocrine dysfunction similar to that seen in primary affective disorders. To confirm our hypothesis, further testing using dexamethasone suppression and TRH stimulation, along with determination of UFC levels, seems to be indicated. Meanwhile, physicians may benefit by reevaluating their use of antipsychotic medications for patients who have symptoms of primary affective disorders.

Diazepam Withdrawal Syndrome: A Case with Psychosis, Seizure, and Coma

BY MARK L. DE BARD, M.D.

Since its introduction into clinical use in 1963, diazepam has been considered nonaddicting. However, for years the literature has been sprinkled with reports to the contrary. Phenobarbital was also initially thought to be safe and free of addictive properties until accumulated clinical experience over many years proved otherwise (1). Amphetamine, introduced clinically in 1935, was not realized to be addictive until about 1958.

Numerous authors have warned of the existence of a diazepam withdrawal syndrome (1–3). At least 8 cases of acute organic brain syndrome thought to be secondary to withdrawal of diazepam have been described (4, 5). Thirteen cases of grand mal withdrawal seizures have been reported (3–9). One case of prolonged coma following diazepam withdrawal was found (10).

I will describe a case that combined an acute organic brain syndrome and prolonged coma in three separate instances, along with a grand mal seizure in one instance, in a patient who could not be withdrawn from diazepam.

Case Report

The patient, a 56-year-old man, was seen in the emergency room for a suicide gesture. The mental status exam showed him to be much more apathetic, withdrawn, and depressed than he had seemed during an examination 2 weeks earlier, and he had obvious suicidal ideation. His medications included diazepam, 10 mg q.i.d.

The patient gave no personal or family history of epilepsy or seizures. He used alcohol only socially, and this was confirmed by his relatives for the 3 weeks that he stayed with them before his admission.

The patient was admitted to the psychiatric unit with the diagnosis of involutional depression. All prehospital medications were continued with the exception of diazepam, and imipramine was started. He improved over the next week. However, 8 days after admission, he became despondent and preoccupied, with staring behavior. He complained of numbness and became very unsteady on his feet.

Over the next 2 days, the patient experienced visual hallucinations and disorientation. He became very restless, started perspiring, and suddenly had a grand mal seizure. A complete seizure workup was normal. He remained deeply comatose for the next 6 hours. His previous physician was contacted and the following history was obtained.

The patient had been taking diazepam, 80 mg/day, from 1969 through 1973. In 1973 he had an elective medical hospitalization. The diazepam was discontinued during this hospitalization, but no other medications were changed. He was not given tricyclic antidepressants then, and he had never had a seizure to that point.

Ten days after that admission the patient reportedly developed seizures and lapsed into coma for an unknown length of time. A neurosurgeon gave him intravenous diazepam. Over the next 24 hours the patient's sensorium cleared and he recovered completely. He was discharged with the diagnosis of acute brain syndrome secondary to diazepam withdrawal and was maintained on diazepam, 10 mg q.i.d.

Based on this information, the patient was given diazepam, 5 mg I.M. Several hours later he was sufficiently alert to take diazepam orally, 5 mg every 8 hours. Over the next 24 hours he began eating and returned to a normal mental status.

During the next 9 days the diazepam dosage was gradually decreased and then stopped. Imipramine was restarted. Ten days later, he began to show the same withdrawal symptoms and became comatose, with frequent jerking movements.

He was given diazepam, 5 mg I.M. The twitching stopped, but he remained deeply comatose, with flaccid extremities and no response to pain. He was given a second dose of diazepam, 5 mg I.M. Two hours later he had awakened enough to request some food. He improved over the next 18 hours and again attained a normal mental status. Diazepam was given in a maintenance dose of 5 mg q.i.d., and he was discharged 5 weeks after admission. He has been maintained on diazepam, and follow-up for 11 months showed no further problems.

Comment

The occurrence of a diazepam withdrawal seizure is not without precedent. Such convulsions have occurred 2–12 days after discontinuation of the medication, with an average of 8 days.

The persistence of coma is very unusual; the only similar case I am aware of occurred after high-dose therapy for tetanus (10). The occurrence of coma three times and the dramatic resolution within hours of diazepam administration seem to confirm this as withdrawal coma. This would seem to be a very important effect that has not received much medical attention.

One might say this patient's mental changes resulted from acute psychotic depression or even from the anticholinergic effects of imipramine. However, the temporal relationships do not favor these interpretations, and imipramine was not given the first time the patient underwent withdrawal. The recurrence of the same mental symptoms three times 8–10 days after discontinuation of diazepam firmly supports the diagnosis of acute organic brain syndrome secondary to drug withdrawal.

Discussion

It has been almost 15 years since the introduction of diazepam, and its addictive potential is just beginning to be realized. A physical dependence seems to devel-

op in some patients who use the drug on a chronic basis (probably a minimum of 2 weeks). More severe withdrawal symptoms seem to be associated with a longer period of use and higher doses, but there is marked individual variation.

For many years it has been said that the "anxiety state" many people experience after they stop diazepam is just a return to their premedication state (3, 6). Maletzky and Klotter (3) question the feasibility of such a distinction between physiologic dependence and the recurrence of patients' original symptoms. Certainly, the more severe symptoms of withdrawal that I have described are no longer difficult to identify.

In conclusion, to prevent the development of even minor physical dependence, one should refrain from outpatient prescription of diazepam for longer than a month in any individual patient. Similarly, one should not abruptly discontinue diazepam treatment for patients who have been on long-term and/or high-dose therapy.

Panic Attacks: Diagnostic Evaluations of 17 Patients

BY STEPHEN F. PARISER, M.D., BRUCE A. JONES, M.D., EMIL R. PINTA, M.D., ELIZABETH A. YOUNG, M.D., AND MARY E. FONTANA, M.D.

There are growing numbers of reports on anxiety-panic syndromes and their relationship to cardiovascular disorders such as hyperdynamic beta-adrenergic states and mitral valve prolapse syndromes (MVPS) (1–3). We recently reported on a case involving an association between panic disorders and MVPS (1). Panic attacks have also been noted to occur in affective disorders (depression) (4).

Treatment of panic attacks has challenged the medical community. Tricyclic antidepressants, monoamine oxidase (MAO) inhibitors, beta-blocking agents, and psychotherapy have all been reported effective to some degree in treating patients with panic attacks (5–7). Recent changes in psychiatric nosology have encouraged specific treatment in specific syndromes by way of exclusion-inclusion criteria. The draft third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (8) incorporates a variety of syndromes, referred to as anxiety disorders, all associated with one or more types of anxiety symptoms. Proper use of these diagnostic categories requires that the physician inquire as to the presence or absence of panic attacks. This is important because there is a need to differentiate patients with different forms of anxiety-related symptoms.

Anxiety symptoms are related to autonomic nervous system activity and to cognitive-affective functioning. Anxiety symptoms (panic or other symptoms) can be signs of any number of disorders. Our work focuses on patients whose chief complaint is panic attacks. We raise questions about the etiology of panic attacks, their relationship to cardiac and psychiatric disorders, and their treatment.

Method and Subjects

The subjects were adult patients who consulted one of the psychiatrist authors (S.F.P., B.A.J., E.R.P., or E.A.Y.) during a 6-month period with a chief complaint of panic attack symptoms. There were 24 patients, 11 men and 13 women, who had panic attacks diagnosed by the Research Diagnostic Criteria (9). Their ages ranged from 21 to 53 years. All were interviewed by a psychiatrist. Because of the nature of their symptoms, cardiology evaluation, echocardiogram, and thyroid studies (T_3, T_4, and FTI) were requested. Seven patients did not complete the full evaluation. We will report here on the 17 patients who completed the

psychiatric evaluation, echocardiograms, and cardiology evaluations. Twelve of these 17 patients completed the thyroid studies.

Results

The RDC diagnoses made by psychiatric interview in these 17 patients were panic disorder (N=10) and major depression (N=5) (see table 1). No patient met RDC for schizophrenia, schizo-affective disorders, mania, hypomania, or Briquet's disorder. Depression was particularly common in women with panic attacks. Eight of 9 women but only 2 of 8 men met RDC for major depression at the time of the interview.

Cardiology evaluation showed that 6 patients had definite MVPS by cardiac auscultation and echocardiogram. Two other patients had positive echocardiograms and cardiac auscultatory findings that suggested but did not confirm MVPS. No patient had abnormal thyroid studies.

Comment

This clinical investigation suggests that the panic attack is a symptom complex with a variety of underlying etiologies. Panic attacks may be associated with affective illness, particularly in women, and with cardiovascular syndromes such as MVPS in addition to panic disorder. Our results suggest that clinicians should consider these diagnoses in patients with panic attacks. The exact relationship between MVPS, affective disorders, and panic attacks is controversial, but there may be common involvement of the autonomic nervous system. A relevant exclusion clause in the RDC for panic disorders eliminates patients who have other disorders that can account for panic symptoms. Therefore, if MVPS is a cause of panic attacks, only 6 of the 17 patients would qualify for the diagnosis of panic disorder, because 4 patients who met other RDC for panic disorder also had definite MVPS. The relationship between MVPS and panic attacks needs clarification. This study suggests that as the diagnosis of other disorders such as MVPS and affective illness is aggressively pursued, fewer patients may be diagnosed as having RDC-defined panic disorder. The diagnosis of associated disorders may permit better choice of pharmacologic treatment and better understanding of the specific pathophysiology of the syndromes.

Childhood Cross-Gender Behavior and Subsequent Sexual Preference

BY RICHARD GREEN, M.D.

Are there childhood behavioral predictors of adolescent and adult homosexual orientation? Until the past decade there were essentially no data to support a positive response to this question. The answer is beginning to emerge more clearly as a result of both retrospective and prospective research. I have been primarily engaged in the latter.

Relevant retrospective reports are limited in number but clearly provocative. Whitam (1) studied 107 exclusively homosexual males and compared them to exclusively heterosexual males. He found that 47% of the homosexuals recalled being more interested in doll-play than other boys their age, 44% recalled liking to

Received Aug. 14, 1978; accepted Sept. 12, 1978.

cross-dress more, and 42% recalled preferring girls' games and having a female peer group. In contrast, such behaviors were recalled by less than 1% of the heterosexuals.

Before the Whitam report appeared, a psychiatric investigation by Saghir and Robins (2) provided considerable support for a childhood behavioral pattern associated with both male and female homosexuality. Of the males studied, 67% of the 89 homosexuals versus 3% of the heterosexuals reported that they had played mostly with girls and were considered "sissy" or effeminate during boyhood. There was a significantly higher proportion of "tomboys" in the prehomosexual female sample (N=56) both in childhood (70% versus 16%) and adolescence (35% versus 0%), with lack of interest in doll-play discriminating prehomosexual from preheterosexual "tomboys."

In the late 1950s in collaboration with Money I initiated a pilot study of a small sample of behaviorally "feminine" boys (3, 4). Five years ago, I reassessed the few subjects still available from the sample and found them to be primarily homosexual. Because of the small number in the original sample (N=11) and the 55% attrition rate, I reflected on this outcome in a conjectural section of a book (5) but did not consider the data appropriate for a scientific report. More recently, Money and Russo (6) reinterviewed 5 of these persons and confirm that this sample remains homosexually oriented.

In collaboration with Stoller, I began a comprehensive longitudinal study of psychosexual development in two initially disparate male samples (7, 8). One sample consisted of boys who, when initially evaluated, preferred the dress, toys, activities, and companionship of girls, typically role-played as females, and stated their wish to be girls. The 60 boys ranged in age from 4 to 11 years. Fifty were matched with same-age boys from demographically comparable families who, at the time of initial evaluation, showed conventionally masculine behaviors. The extensive disparity in these boys' behaviors and the demographic similarities of the sample have been reported elsewhere (5, 8).

Some of these boys are now in early to mid-adolescence. More of the previously "feminine" boys are in this age group because the contrast group was generated later and thus is younger. This is the initial preliminary report describing the emerging sexuality of the older members of the "feminine-boy" sample.

Data on Previously "Feminine" Boys

These preliminary data on the "feminine-boy" sample will be divided into four areas: masturbation fantasies, reported erectile response to heterosexual stimuli, reported erectile response to homosexual stimuli, and interpersonal genital experiences.

For the 11 boys who have masturbated, none has exclusively homosexual associated fantasies, 4 have both homosexual and heterosexual fantasies, and 4 have exclusively heterosexual fantasies. Three boys report no fantasies. One boy who does not masturbate has nocturnal emissions that are activated exclusively by homosexual imagery, and another who does not masturbate has emissions activated by heterosexual imagery. Thus, 50% of the boys who have fantasies that accompany masturbation or nocturnal emissions respond to homosexual fantasies.

Twelve boys have viewed photos of nude males: 3 report that they usually get erections when viewing such a stimulus, 5 sometimes get erections, and 4 do not get erections. Of the 18 boys who have viewed photos of nude females, 6 usually get erections, 9 sometimes, 1 rarely, and 2 never. Thus, 3 of these 18 boys typically do not respond with erections to these heterosexual stimuli.

Of the 9 boys who have engaged in intercourse or heavy genital petting, 1 has had such experiences only with males, 5 with both males and females, and 3 with females only. Thus, two-thirds of this group is homosexually or bisexually oriented at present.

It is clear that feminine boyhood behavior, as defined by clothing, toy, peer group, activity, and role-playing preferences, does not consistently predict later homosexual orientation. However, from preliminary data, it does appear to load in favor of such an outcome in some persons.

"Tomboys"

Next, a word about the developmental course of "tomboyism." Certainly, "tomboyism" is more common than sissiness and more often converts to more conventional feminine behavior in adolescence. However, at least one study (2) suggests that "tomboy" behavior may be associated with later feminine homosexual orientation.

I am conducting a large-scale developmental study of "tomboys" (9). Previously, I initiated a small pilot study (5), without a control group, similar to the pilot study I did with Money. The sample consisted of 4 girls who insisted on wearing boys' clothes, were very interested in participating in sports, rejected doll-play, had a male peer group, and stated they wished they were boys. Their degree of "tomboyism" seemed greater than is typical for children commonly termed "tomboys." Recently, follow-up data have been collected on these 4 subjects, who are now midteenage or young adult.

One is living as a man, has had a hysterectomy, and is receiving exogenous androgen. Two are varsity athletes; one is behaviorally asexual, and the other has recently "discovered boys." Both are described by their parents as "still walking and sitting like boys" and avoiding cosmetics and conventionally feminine attire. The fourth is described as conventionally feminine and very interested in dating boys. Thus the range is considerable and, as with the Green and Money series, these data from a small sample with no controls must await more comprehensive follow-up with large samples.

Discussion

Our data so far indicate a moderate amount of homosexual fantasy, arousability, and overt behavior in a sample of boys who were previously "feminine." However, of considerable importance is the current variation in sexual orientation in these boys. One mid-adolescent is a "drag queen" and has had an extensive series of same-sex partners. One is genuinely bisexual, with an equal distribution of erotic fantasies and overt behaviors involving males and females. One prepubertal boy reports erections in response to fantasies or pictures of nude males but not females, although he has had no interpersonal genital experience. Others report an exclusively heterosexual orientation.

This variation in outcome is noteworthy. Clearly all boys who show behavioral patterns considered "feminine" are not prehomosexual. Parents of boys whose behavior does not fit the conventional stereotype of "masculinity" should not be rendered anxious by the belief that their children are prehomosexual. I have elsewhere (10) reviewed data supporting the conclusion that homosexuality is not a mental illness and does not predispose to poor social or psychological adjustment. However, many parents do become grief-stricken if they believe their children are or will become homosexual. Thus I feel it important to stress the markedly atypical early childhood behavior of the sample described here, and the considerable variability in their later sexual behaviors.

Our research task in the coming years goes beyond collecting sexual history on the remainder of the sample and extending the data on the subjects reported here. The major challenge is examining the early life behavioral and psychological test data on the sample, features of their parents, and developmental life events leading to adolescence and young adulthood. We hope to discriminate among those previously "feminine" boys who emerge with a primarily homosexual, bisexual, or heterosexual orientation.

Serum Prolactin and Clinical State During Neuroleptic Treatment and Withdrawal

BY THOMAS P. LAUGHREN, M.D., WALTER ARMIN BROWN, M.D., AND BRADFORD W. WILLIAMS

Serum prolactin is elevated both acutely (1) and chronically (2) by neuroleptic drugs. The prolactin-elevating effect of neuroleptics correlates well with their antischizophrenic potency (1) and appears to correlate better with neuroleptic-induced sedation and EEG changes than does neuroleptic plasma level or dose (3). Clinical improvement during neuroleptic treatment does not appear to correlate well with prolactin elevation in most patients (4). This finding may be explained by the narrow range of sensitivity of the prolactin-elevating response to neuroleptics. An alternate approach to examining the relationship between prolactin concentration and clinical state is to monitor patients during withdrawal from neuroleptic treatment. The present report describes the relationship between serum prolactin and psychological state during chronic treatment with thioridazine and haloperidol, withdrawal from treatment, and return to treatment.

chronic schizophrenia (N=8), hysterical neurosis (N=1), and alcoholism (N=1). Eight patients had been taking thioridazine in the range of 50–400 mg/day (mean=212 mg/day) for a period of 4 months to 14 years (mean=5.1 years). Three patients had been taking haloperidol in a range of 15–20 mg/day (mean=17 mg/day) for a period of 1–3.5 years (mean=2.7 years). Patients were taking no other medication. They continued their usual dose of medication for a 2-week baseline period (chronic), were given matched placebos for 4 weeks (placebo), and returned to their baseline dose for 4 weeks (acute). Four patients had shortened placebo periods because of the development of symptoms. A blood sample was obtained once weekly at 8:00 a.m. from patients who had fasted overnight and had been awake for at least 1 hour. The Brief Psychiatric Rating Scale (BPRS) and the Profile of Mood States (POMS) were completed for each patient.

Serum prolactin was measured by double antibody radioimmunoassay. All samples from the same subject were measured in duplicate in the same assay. Both the interassay and intraassay coefficients of variation were less than 7%. Laboratory personnel were blind to the study protocol.

Results

The mean serum prolactin concentrations (see table 1) were elevated during chronic (13.2 ng/ml) and acute (14.8 ng/ml) treatment and differed significantly from the placebo prolactin concentration (5.8 ng/ml, $F=6.8$, $p<.01$). The patients with the lowest prolactin concentrations chronically (less than 6 ng/ml) (patients 1, 2, and 3) showed the greatest relative clinical worsening during the placebo period (more than 50% increase in POMS scores, $p=.006$, Fisher exact probability test; more than 20% increase in BPRS scores, $p=.024$). These patients had BPRS scores similar to the other patients during the chronic treatment period. All 3 had schizophrenic diagnoses. During placebo, patient 1 developed delusional thoughts and bizarre behavior and patient 2 developed auditory hallucinations, insomnia, and marked anxiety. Although patient 3 did not show clear psychotic symptoms during placebo, he did become very anxious, sleepless, and more withdrawn. These patients also had the lowest prolactin concentrations during the placebo period (less than 4 ng/ml) and the greatest relative improvement during acute treatment (more than 50% decrease in POMS scores, $p=.006$). Patient age, drug, dose, and duration of treatment were not related to prolactin concentration or change in clinical state.

Nine of the 11 patients had lower mean serum prolactin concentrations during chronic than acute treatment ($p<.05$, sign test). The differences in prolactin concentration ranged from 4%–54% lower chronically than acutely. The same patients (patients 1, 2, and 3) showing the greatest clinical change during placebo and acute treatment also showed the greatest difference in prolactin concentration chronically compared to acutely (more than 39% lower chronically, $p=.024$).

Discussion

This study confirms earlier findings that male patients taking neuroleptics acutely or chronically have significantly higher serum prolactin concentrations than during drug-free states. The lower prolactin concentrations seen chronically compared with acutely in some patients are suggestive of at least partial tolerance to the prolactin-elevating effect. An earlier study (2) reported lower prolactin concentrations in female patients taking neuroleptics chronically (5 years or more) as compared with female patients taking equivalent doses acutely (2–4 weeks).

Other groups have not found tolerance effects to prolactin elevation, but these studies either examined prolactin concentrations over shorter time periods (1, 4) or did not maintain neuroleptic doses at fixed levels (4, 5). Our finding of tolerance to the prolactin-elevating effect of neuroleptics must be considered tentative until more data relevant to this effect are collected. Tolerance to the biochemical and behavioral effects of

neuroleptics in the basal ganglia has been demonstrated in both animal (6) and human (7) studies.

The patients with the lowest prolactin concentrations during the chronic and placebo periods also showed the greatest relative clinical worsening after drug withdrawal and the greatest relative clinical improvement after drug resumption. These patients also showed the greatest apparent tolerance to prolactin elevation. Possibly these patients represent a subgroup of schizophrenic patients with an overactive and labile dopaminergic system, which is reflected in generally lower serum prolactin concentrations and the development of partial tolerance to prolactin elevation. The increasingly ineffective dopaminergic blockade occurring in these patients could explain their greater vulnerability to relapse when completely withdrawn from neuroleptics. Alternatively, the patients showing apparent tolerance may not have been taking their medications regularly during chronic treatment and were more vulnerable to drug withdrawal on this basis. In either case, lower prolactin concentrations predicted greater susceptibility to clinical change with either drug withdrawal or treatment. Prolactin concentrations should be further explored as possibly useful predictors of clinical response following drug withdrawal.

Use of Bethanechol Chloride with Phenothiazines: A Case Report

BY DANIEL S.P. SCHUBERT, M.D., PH.D.

Everett (1) reported the use of bethanechol chloride to treat dry mouth in patients taking tricyclic antidepressants. I have found this combination useful in several patients. Because dry mouth is also mentioned by patients taking phenothiazines, particularly in combination with antiparkinsonian agents, I thought bethanechol chloride might also counteract the anticholinergic effects in these cases. The case that I will describe is one in which the patient's most troubling symptom was blurred vision produced by the anticholinergic effects of the drugs.

Case Report

The patient, a 47-year-old man with chronic schizophrenia and a history of multiple hospitalizations, seemed relatively clear between episodes and was taking fluphenazine, 5 mg p.o., and benztropine mesylate, 2 mg. When he was hospitalized he was given 20 mg of fluphenazine and 8 mg of benztropine mesylate p.o., but because of his periodic noncompliance, fluphenazine decanoate, 25 mg I.M., was added. The patient began to complain of blurred vision as his psychosis receded. Because of my favorable experience with bethanechol chloride in treating dry mouth in patients given tricyclic antidepressants and because the anticholinergic effect seemed to account for both the blurred vision and dry mouth (2), I prescribed bethanechol chloride, 25 mg. t.i.d. No other change in medication was made at this time. Within 2 days he was able to read small print again. He reported that the dry mouth, which had not troubled him as much as the blurred vision, also remitted, although more slowly. He was continued on the three medications after he was discharged and continued to report that he could read well and had fewer symptoms of decreased saliva output.

Discussion

This case suggests that the anticholinergic side effects of phenothiazines, particularly when these drugs are combined with antiparkinsonian medications, may be effectively treated by the cholinergic bethanechol chloride. Blurred vision is a particularly distressing symptom to many patients who are taking antipsychotics with or without antiparkinsonian agents and will lead many of them to consider discontinuing the medication. I suggest that the use of bethanechol chlorid

with tricyclic antidepressants be extended to other psychiatric medications that have pronounced, troublesome anticholinergic effects.

Caution should be exercised in the use of bethanechol, since it can produce side effects, including epigastric distress, abdominal cramps, diarrhea, and a sensation of tightness in the urinary bladder area (2). Contraindications are listed as asthma, hyperthyroidism, coronary insufficiency, and peptic ulcer (2).

Amantadine-Induced Psychosis in a Geriatric Patient with Renal Disease

BY RICHARD L. BORISON, M.D., PH.D.

It has been widely demonstrated that agents which potentiate central dopaminergic mechanisms, such as amphetamine, are capable of producing schizophreniform psychoses (1). Similarly, drugs that ultimately act by the direct stimulation of central dopamine receptors and drugs that are most commonly used in Parkinson's disease, such as L-dopa or bromocriptine, are also capable of evoking psychotic states as relatively common side effects (2). However, drugs with less potent effects on dopamine systems may under particular circumstances also result in toxic psychotic states, as illustrated in the following case history.

Case Report

The patient was a 70-year-old woman who was admitted to a general hospital for evaluation of a sinus bradycardia. She had a history of hypertension, chronic congestive heart failure, adult onset diabetes mellitus, and chronic renal failure going back more than 10 years. There was no previous history of psychiatric illness. The patient appeared well accommodated to her illnesses: she lived alone, cared adequately for herself, and was actively engaged socially in her church organization. The patient's medications on admission were digitalis (.25 mg daily), α-methyldopa (250 mg q.i.d.), clonidine (.1 mg/day), and 20 units of NPH insulin daily.

Physical examination revealed grade II retinopathy on fundoscopy. There was no thyroidomegaly, bilateral carotid bruits were auscultated, and jugular venous distention of 4 cm was noted. The lungs were clear to auscultation and percussion. Cardiovascular examination showed a blood pressure of 160/80 mm, pulse of 56 beats/minute, and a nonradiating apical grade II/VI systolic ejection murmur. Neurological examination showed no sensory or cranial nerve deficits. The patient had a bilateral resting and intention tremor of the hands; however, there were no changes in muscle tone or pathological reflexes present. On mental status examination the patient was alert, cooperative, and fully oriented. There was no evidence of a mood or thought disorder.

Pertinent laboratory data showed that the patient was in electrolyte balance, thyroid function and blood gases were within the normal range, hemoglobin was 12.3 g, creatinine was 2.9 mg/dl, BUN was 38 mg/dl, 24-hour creatinine clearance was 16 ml/minute, and digoxin level on admission was .77 ng/ml.

The patient was continued on the medications that she was receiving at home and was also given amantadine (100 mg t.i.d.) for suspected Parkinson's disease. Within 48 hours of admission, the patient began reporting that she saw children in her room who were taunting and mimicking her and that she could see her late husband. The patient required restraints to keep her in bed because she repeatedly tried to leave to look under her bed, where she believed she could find her husband making love to another woman. These visual hallucinations were present throughout the day but occurred more frequently at night. During this time the patient remained fully oriented to person, place, and time and showed no impairment in ability to perform such tests of cognitive function as serial sevens. After 2 days of hallucinatory phenomena, the patient's amantadine was discontinued, and within the subsequent 36 hours all hallucinations ceased. The remainder of the patient's hospitalization was unremarkable.

Discussion

Amantadine was originally used as an antiviral agent but was later discovered to be efficacious in mild Parkinson's disease (3). The current belief is that amantadine's mechanism of action is either to release dopamine from storage granules or to block its presynaptic reuptake (4). Although a weak dopaminergic agent that rarely produces changes in mental status (5), it has been shown to have psychotogenic properties when used in a group of elderly patients with renal disease (6). It would thus appear that in the case presented, amantadine, which has a much prolonged half-life in geriatric patients (7), reached toxic levels in the presence of chronic renal disease, which then resulted in the patient's hallucinatory activity.

Received July 27, 1978; accepted Sept. 29, 1978.

Given that the use of weak-acting dopaminergic agents is now advocated in the treatment of early Parkinson's disease (8) and that amantadine has also been advocated for the treatment of neuroleptic-induced extrapyramidal side effects (9), this drug should be used only after careful clinical evaluation of renal function, particularly in the case of the geriatric patient.

Sudden Death in a Patient Taking Haloperidol

BY RICHARD KETAI, M.D., JOHN MATTHEWS, M.D., AND JOHN J. MOZDZEN, JR., M.D.

To date, haloperidol has not been associated with sudden death, although this outcome has been suggested for phenothiazines. Deaths associated with phenothiazines have been attributed to hyperpyrexia (1), vasodilation and hypotension (2), and aspiration and asphyxia (3). Cardiac toxicity (4, 5) and generalized inhibitory effects on multiple brain regulatory centers have been hypothesized but have not been documented as causes of death in patients taking phenothiazines. We are reporting a case of sudden death in a young woman who received rapid tranquilization with increasing doses of haloperidol and for whom no obvious cause of death was found.

Case Report

The patient, a 35-year-old married woman with 3 children, had had no previous psychiatric problems or significant medical history. She was admitted to the acute inpatient service following a 2-month history of gradually increasing outgoing behavior, atypical of her usual reserved style, culminating 3 days before hospitalization in overtly psychotic behavior. This consisted of insomnia, religious preoccupation, agitation, and talkativeness. Two days before admission she received 200 mg of I.M. chlorpromazine in her local hospital emergency room with no effect.

At admission the patient was agitated and suspicious, unable to sit still, and had rapid speech and flight of ideas that were largely incoherent and illogical. Her affect was anxious and labile, and she was preoccupied with God and dying. Although she recognized family members, she was so disorganized and uncooperative with mental status testing that recent memory and orientation could not be accurately assessed.

Physical examination revealed no abnormalities except hyperreflexic knee jerks. She would not cooperate with fundoscopic examination or with blood drawing for laboratory screening despite repeated attempts by medical staff.

A course of rapid tranquilization with haloperidol was begun using a liquid concentrate. On the first day the patient received 10 mg every half hour up to 50 mg; on the second day of hospitalization she received 70 mg. Because she did not respond, progressive tranquilization was planned and she was given 140 mg over the next 12 hours. She had a mild dystonic reaction that responded quickly to 2 mg of benzotropine p.o., which was continued at 1 mg b.i.d. Her mental status did not change and she slept only 4 hours that night. On the fourth day of hospitalization she was as excitable as she had been at admission. She took 20 mg of haloperidol each hour for 4 hours and went to sleep. Her vital signs were normal at this time. She was checked every 15 minutes and appeared to be sleeping comfortably. Two hours after the patient fell asleep the nurse observed that she looked cyanotic. Her respiration and pulse had suddenly stopped. Immediate attempts at resuscitation by the cardiac arrest team were unsuccessful.

Autopsy findings revealed a 3-cm adenocarcinoma of the colon but no evidence of metastases. There was nonspecific mild edema of the lungs, brain, and liver; this was thought to be due to the cardiopulmonary resuscitation. Urinalysis showed that the only drugs present were haloperidol and benzotropine.

Discussion

Neuroleptic-related death is a controversial topic because sudden deaths, even in unmedicated psychiatric patients, are sometimes unexplained. Peele and Von Loetzen (6) pointed out the existence of fatal "Bell's mania" or "lethal catatonia" before the medication era. Available investigative techniques for infectious and metabolic disturbances at that time, however, may not have been sufficient to detect an organic cause of psychosis and death. Even today, sudden unexplainable deaths occasionally occur in supposedly healthy people, e.g., the recently reported "sick sinus syndrome" (7). Patients with acute psychoses of undetermined origin could hypothetically be susceptible to sudden death reflecting neurologic dysfunction with secondary cardiac or respiratory pacing abnormalities.

Although most reviews of sudden death in phenothiazine-treated patients turn up negative autopsy findings (8) and although undetected neurologic or other unknown organic factors may be the cause of death, it is important to report sudden deaths in patients on various medications even if no cause and effect relationship is apparent. To date we are aware of no published cases related to haloperidol alone.

The manufacturer of haloperidol has abstracted cases of 12 fatalities in patients on this drug. Ten of these patients had implicated medical problems and/or were simultaneously taking other psychotropic medications, usually in large doses. Only 2 of the patients were taking haloperidol alone, a 19-year-old man who received 35 mg of haloperidol in 1 day and a 21-year-old man who received 25 mg over 4 days. Their deaths were not otherwise explained.

Our patient was being treated by rapid tranquilization in doses higher than were usually found necessary in the protocol developed by Anderson and associates (9). Daily dosages greater than 100 mg are sometimes required for refractory psychotic patients, according to the *Physician's Desk Reference*. Our experience has been doses as high as 150 mg are sometimes required to bring a psychotic episode under control, although ordinarily doses of 20–40 mg/day suffice. This patient showed no effect from 200 mg of I.M. chlorpromazine before hospitalization and did not become the slightest bit sedated on 140 mg of haloperidol the day before she died. The persistence of the psychosis and complete refractoriness to relatively high doses of medication may suggest an occult neurologic malfunction not involving dopamine pathways that would have been blocked by these drugs. Although we have no explanation for this death, there is the possibility that an idiosyncratic response to haloperidol may have occurred.

Civil Commitment and the Rights of the Unborn

BY PAUL H. SOLOFF, M.D., STEVEN JEWELL, M.D., AND LOREN H. ROTH, M.D., M.P.H.

Clinical management of the pregnant psychotic patient is complicated by a potential conflict of interest between the treatment needs of the mother and the risks of such treatment to the unborn child. When the patient's psychosis involves a denial of pregnancy through the third trimester and poses a threat to the life of the unborn child, her right to refuse treatment comes into direct conflict with the best interests of the unborn child, which poses a difficult medicolegal problem for the physician. Although the psychiatric literature contains few guidelines for the clinical care of psychotic patients during pregnancy, recent developments in the law obligate the physician to consider the right of the unborn child "to be well born" (1, 2). In this report, we describe the resolution of this dilemma through the civil commitment of the mother for the duration of pregnancy, an unusual clinical maneuver involving a unique interpretation of commitment statutes.

Case Report

The patient, a 20-year-old single woman, was admitted to the hospital on an involuntary emergency commitment following a physical attack upon her mother during an argument. A diagnosis of schizophrenia, established during a similar admission 2 years earlier, was confirmed by the presence of a formal thought disorder and bizarre delusions in a clear sensorium. Of greatest concern was her psychotic denial of a very visible 7-month pregnancy. The patient maintained she was filled with "gas" and spent long hours in the bathroom trying to relieve her distension. She had joined a health club to lose the weight but had been expelled for diving onto her obviously pregnant abdomen from the diving board. For the 2 years before admission, she had lived at home with her mother, father, and 18-month-old daughter and had been easily managed without medication, despite her persistent psychosis. Although tolerant of the psychosis, her parents were unwilling to accept the denial of pregnancy and neglect of prenatal care. Their attempts to convince her of the pregnancy precipitated arguments that ultimately prompted her combativeness and admission to hospital.

The patient settled into the ward quite comfortably and was cooperative and easily directable. The ease of management raised the question of the appropriateness of initiating drug therapy during pregnancy. Weighing the small but present dangers of medication to the fetus in the third trimester (e.g., neonatal respiratory distress, extrapyramidal dysfunction, and transient neurologic symptoms[3]) against the ease of management in a well-structured environment, we decided to seek her commitment until delivery without active treatment of her thought disorder. The following grounds were presented in support of our request:

1. Involuntary hospitalization was needed to prevent harm to the unborn child through the mother's actions.
2. Confinement of the mother until delivery was the least restrictive alternative that could guarantee monitoring of the pregnancy and ensure a medically safe delivery for both mother and child.

Commitment was requested over the mother's objections in order to protect the child directly and the mother indirectly. Commitment was granted, extended, and sustained in a formal appeal before the Allegheny County Court of Common Pleas. From the 38th week of gestation, the patient was examined every 4 hours for the start of labor. The possibility of inducing labor to ensure a medically controlled delivery was considered. However, this would have required further adversary hearings to prove the patient incompetent and appoint a guardian. The more conservative approach of frequent examination was urged by obstetrical consultants. On her 81st hospital day, the patient requested sanitary napkins from the staff, stating she had finally resumed her menstrual periods. She was found to have ruptured membranes and was in active labor. She was rushed to a nearby women's hospital and delivered a healthy male child within the hour. The newborn infant, finally a person within his own right, was taken into the custody of the Child Welfare Department, initiating yet another round of adversary hearings in which the mother, recognizing the reality of the birth, sought custody of the child she had denied for 9 months.

The patient was returned to the psychiatric hospital following postpartum care and was started on perphenazine, 24–64 mg/day for 1 month, with no remission of her thought disorder. Three months after discharge, she has shown no clinical response to perphenazine, maintained at 32 mg/day.

Discussion

Commitment in this case was granted to afford protection to an unborn child over the protest of the mother. In so doing, the court upheld the welfare of the unborn as if it were already a "person-in-being," with rights to protection under the broad principle of *parens patriae* (the state's interest in protecting persons unable to protect themselves).

Despite the rigorous intent of Pennsylvania's commitment statutes, which require 1) evidence of danger to self or others in the preceding 30 days, and 2) a high probability of recurrence of danger in the next 30 days if treatment is refused, judicial interpretation has proven flexible in the face of clinical or social necessity. A review of the legal status of the unborn suggests that this case represents an interpretation of the commitment statute that is both unique and consonant with the growing medical and social concern for protection of the unborn.

The Rights of the Unborn

The unborn child has been treated with great inconsistency in the different branches of law (4). In *Roe v. Wade* (5), the Supreme Court upheld the mother's "right to privacy"—to obtain an abortion—over the state's interest in preserving the life of the fetus during the first 6 months of pregnancy. Justice Blackmun held that the word "person," as used in the 14th Amendment, did not include the unborn. However, the same decision recognized the interest of the state in the unborn child after the sixth month, maintaining a basis for protection under the doctrine of *parens patriae*.

Under this broad doctrine, conflicts of interest between mother and unborn child have been heard in cases involving the religious objections of the mother to medical treatment for the child. In *Hoener v. Bertinato* (6), the court awarded custody of a child in utero to a welfare department for the purpose of administering a needed blood transfusion at the time of birth over the religious objections of both parents. Similarly, in *Raleigh Fitkin-Paul Morgan Memorial v. Anderson* (7), the court compelled a Jehovah's witness to submit to blood transfusion to protect the life of an unborn child. The child's right to life was placed above the parent's right to free practice of religion.

Reviewing the fate of the unborn child in mothers addicted to opiates, Densen-Gerber and associates advocated the use of civil commitment for treatment and detoxification of the mother, recognizing the unborn child as a person-in-being with a "right to be well born" (8). Commitment of the pregnant psychotic patient described here represents an affirmation of this principle by the court and a clinical use of the statute to safeguard both mother and child to term.

The Effect of Lithium Treatment on Thyroid Function in Patients with Primary Affective Disorder

BY JUN TAE CHO, M.D., STANLEY BONE, M.D., DAVID L. DUNNER, M.D., EDWARD COLT, M.D., AND RONALD R. FIEVE, M.D.

The purpose of this study was to investigate the incidence of clinically significant thyroid gland dysfunction among a group of affectively ill patients who were attending a lithium clinic. Isolated cases of goiter during treatment with lithium carbonate were first reported by Danish and Swedish investigators in 1967, and the thyroid effects of lithium have been reviewed extensively by Shopsin (1). Three major thyroid effects of lithium treatment have been noted: asymptomatic thyroid gland enlargement, clinically significant hypothyroidism, and a few cases of thyrotoxicosis. Although these effects of lithium on the thyroid gland have long been demonstrated, the incidence of lithium-related thyroid dysfunction has not been systematically reported from large lithium treatment centers.

Received July 5, 1978; revised Sept. 11, 1978; accepted Sept. 29, 1978.

Supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-21586 from the National Institute of Mental Health, by the Columbia-Millhauser Depression Center, and by the Foundation for Depression and Manic Depression.

Method

The study was conducted in the Lithium Clinic of the New York State Psychiatric Institute. All patients had primary affective disorder (2) and were further classified into bipolar and unipolar subtypes (3, 4). Patients who had four or more affective episodes yearly were separately noted as rapid cyclers (5). All subjects participated in the study on a voluntary basis.

Patients were routinely asked about their use of medication, including lithium, other psychiatric medi-

0002-953X/78/01/0115/02/$00.35 © 1979 American Psychiatric Association

cation, and drugs for medical indications. All patients who were taking supplemental thyroid hormone were studied regarding the medical indication for use of thyroid medication, duration of thyroid treatment, and history of thyroid disease before initiation of lithium treatment. These questions were also asked of a comparison group of patients who were evaluated before lithium treatment or who were relatives of index patients and had a diagnosis of primary affective disorder but were not taking lithium.

Results

The clinic sample consisted of 195 patients (80 men and 115 women). Twelve of these patients (1 man and 11 women) had thyroid disease and were taking thyroid medication in addition to lithium. Five patients (1 man and 4 women) had started thyroid treatment before they were given lithium. Thus, 7 women (6.4% of the lithium-treated women) developed clinically significant hypothyroidism after they started taking lithium.

Further investigation revealed that 5 of these 7 postlithium thyroid patients were rapid cyclers. Only 16 of the 115 women attending the clinic were rapid cyclers, so the incidence of postlithium thyroid medication use was significantly higher among rapid-cycling women than non-rapid-cycling women (31.2% versus 2.1%, $\chi^2=7.64$, $p<.01$). Excluding rapid cyclers, thyroid medication was used by 4 women before lithium treatment and by 2 other women subsequent to treatment.

The comparison group consisted of 39 women and 23 men who had primary affective disorder and no history of lithium treatment. None of the men and 2 of the women were taking thyroid. Of the 3 women who were rapid cyclers, none was taking thyroid. Thus, the incidence of thyroid use among these non-rapid-cycling women in the comparison group (5.6%) is quite similar to that among non-rapid-cycling women patients before lithium treatment (5.1%).

No cases of thyrotoxicosis subsequent to lithium treatment were reported by these patients. All instances of hypothyroidism had been documented by laboratory studies of thyroid function.

Discussion

Our data suggest that there may be a subgroup of patients—women with high frequencies of affective episodes—who are particularly prone to develop hypothyroidism while they are taking lithium carbonate. Other patients do not appear to have increased incidences of hypothyroidism secondary to lithium of sufficient clinical significance to warrant treatment with additional thyroid medication. It appears that about 5% of affectively ill women are taking thyroid before lithium treatment is started and that a few additional instances of hypothyroidism occur during ensuing years of lithium treatment. A third finding from our study is that the thyroid dysfunction was primarily limited to women.

The data from this study are presented because they represent a large number of patients and they may be useful background material for other clinicians as well as investigators from other large lithium research centers. We are particularly interested in data from other centers regarding the incidence of thyroid medication use among lithium-treated rapid-cycling women. Confirmation of our findings may lead to fruitful research regarding the difficulties in treating such patients (5).

Orofacial Movement Disorder: Tic or Tardive Dyskinesia?

BY BENNETT L. LEVENTHAL, M.D., AND MEREDITH ALDEN, PH.D.

Orofacial dyskinesias are associated with a variety of physical and psychological conditions. Such cases present the clinician with the potential for an expansive differential diagnosis. For patients who are taking psychotropic medications, much concern focuses on tardive dyskinesia (1-3). However, it is essential that patients with movement disorders be assessed carefully for possible etiologies other than tardive dyskinesia before treatment is initiated.

Received July 10, 1978; accepted Aug. 7, 1978.

Case Report

A 48-year-old divorced woman had worked as a reservations clerk before her admission to a nearby psychiatric

 0002-953X/78/01/0116/03/$00.40 © 1979 American Psychiatric Association

hospital in September 1977. At admission she had masked facies, a "drugged appearance," fine tremor, parkinsonian gait, and vegetative signs of depression that had been progressing since the sudden, unexplained departure of her boyfriend of several years. Evaluation revealed a normal EEG and CT scan and a full-scale I.Q. of 83 on the Wechsler Adult Intelligence Scale. The patient denied recent alcohol or drug use. She was diagnosed as having depressive neurosis, passive-dependent personality, and parkinsonism. During her hospitalization she was treated with imipramine, benztropine, and thioridazine. After returning from a 10-day stay at home, she was found to have an elevated tricyclic antidepressant plasma level (imipramine plus desipramine = 540 ng/ml). She failed to make significant clinical improvement and was transferred to Duke University Medical Center in late November 1977. All medications were discontinued and neurologic evaluation was negative except for a diffusely abnormal EEG. The patient had no parkinsonian symptoms but appeared to be severely depressed and had orofacial movements characterized by darting tongue movements, lip-pursing, chin quivering, and bucco-mandibular masticatory movements. Based on her age and history, the patient was given presumptive diagnoses of tardive dyskinesia and depression and was started on 600 mg/day of deanol and 6 g/day of L-tryptophan for the respective problems. By mid-January, her affect and movement disorder were unchanged. However, there was improvement in the EEG.

The patient was only hesitantly able to engage in psychotherapy. On occasion, she would wring her hands and cry, without explanation. These episodes were immediately preceded by increases in the orofacial movements. Psychotherapeutic efforts led her to speak about her disappointments in life, which centered around unmet dependency needs and, in particular, her frequently absent mother. As the patient recalled and worked through the rage she felt toward her mother, the orofacial movements and hand wringing diminished. When this was observed, she seemed relieved to report a maternal prohibition against crying and other expressions of affect. She remembered that when she was a child her chin would quiver as she fought back tears and expression of anger toward her mother.

Her abnormal orofacial movements had ceased by mid-February, despite the discontinuation of deanol and the use of doxepin (at therapeutic plasma levels) to control a persistent depression. However, the abnormal movement returned when she prepared to go home. No medications or dosages had been changed and her neurologic status was also unchanged. Remission occured rapidly with review of the previous psychotherapeutic work. By the time of discharge her I.Q. scores and EEG were well within the normal range and she was asymptomatic for movement disorder and depression.

Discussion

The differential diagnosis of orofacial dyskinesias includes basal ganglion disease, metabolic disease, post encephalitic syndromes, schizophrenic stereotypies, and drug-induced conditions related to agents such as L-dopa, neuroleptics, and anticholinergics (1). Of significance in this case are recent reports of oral dyskinesia associated with imipramine treatment (4, 5). Because of the initial encephalopathy, it could be argued that the patient's movement disorder was not psychogenic. However, the resolution of the movement disorder did not parallel the resolution of the encephalopathy, and there was no residual neurologic deficit. In addition the brief exacerbation and rapid remission did not correlate with any changes in the patient's neurologic status, but the remission closely paralleled the patient's progress in psychotherapy.

There is compelling evidence that this patient had a psychogenic tic rather than a neurologic disorder. Psychogenic tics can present as a variety of movement disorders. They are usually seen as intermittent, sudden, repetitive movements that occur without external stimuli. Tics can become automatic behaviors that are modifiable by treatment. However, even in the most successfully treated case, the tic may recur when the patient is under significant stress (6). Ferenczi (7) suggested that many tics are developed as means to avoid suffering and that they are often difficult to differentiate from compulsive acts. Abraham (8) agreed that tics may not be distinguishable from compulsive acts, but he pointed out that the patient with a tic may not attribute psychological significance to the tic and does not fear disaster if the compulsive act is omitted. Like the compulsive act, the tic may involve a hostile as well as an erotic component. The tic then represents an attempt to adapt to an "instinctual conflict" (9). In the case we have described, the patient experienced a conflict between the drives for love and dependency and the expression of hostile aggressive impulses toward her mother and others who frustrated these drives. The additional frustration of the maternal prohibition of expression of affect led the patient to adopt a motor response to ward off this conflict. This patient came to substitute the small muscle activity for other expressions of affect and aggression secondary to the fear of punishment or loss of love. This motor response had been present since childhood, and the loss of her boyfriend had intensified these fears, precipitating her depression and exacerbating the tic. In psychotherapy the patient began to work through these conflicts and was thus able to give up her tic and use more effective adaptive mechanisms.

Treatment of movement disorders varies greatly with diagnosis. The literature on therapy for tardive dyskinesia is, thus far, controversial. Tics are sometimes successfully treated with haloperidol; this patient responded to insight-oriented psychotherapy. Because treatment for one movement disorder may worsen another, it is essential that each patient be evaluated carefully before therapy is started. With symptomatically similar disorders requiring significantly different treatments, treatment must be prescribed on the basis of diagnosis rather than clinical presentation.

Case Report: Symptomatic Mania and Phencyclidine Abuse

BY ARNOLD ROSEN, M.D.

The increasing prevalence of phencyclidine abuse, with its psychiatric consequences, has become a challenge to the clinical psychiatrist. The pharmacology of phencyclidine and its associated toxic mental conditions were recently reviewed by Showalter and Thornton (1). In 1977, Slavney and associates (2) reported two cases of symptomatic manic states following use of phencyclidine (commonly called PCP or angel dust). They emphasized the following points:

1. The manic-like psychosis took place in clear consciousness.
2. Symptomatology met research criteria proposed by Feighner and associates (3) and by Abrams and Taylor (4).
3. Symptoms persisted longer then would be expected on the basis of the drug's half-life.
4. Patients had no prior psychiatric history.
5. Patients had no family history of affective illness.

In addition, their patients' psychoses responded minimally to neuroleptics but resolved when lithium carbonate treatment was instituted. The following case report describes a post-PCP symptomatic manic episode that began to respond only after ECT.

Case Report

The patient, an 18-year-old man with no psychiatric history, came from an intact middle-class family that did not have a history of affective illness. The patient was outgoing, played on the school basketball team, and was a below average to average student. He had experimented with many street drugs 3 months before his admission: cocaine, opium, PCP, and marijuana. His psychosis began after he smoked PCP 1 week before his admission. His family had noted an immediate change in his behavior. He initially seemed withdrawn and had difficulty concentrating, but after a few days he became agitated, with hyperactivity, insomnia, thought disorganization, and paranoid delusions. He was hospitalized and required increasing doses of haloperidol (up to 60 mg/day) for 4 days before his agitation subsided. He then developed a symptom picture indistinguishable from catatonic schizophrenia: catalepsy, posturing, mutism, negativism, and stupor. On the eighth hospital day, this symptom picture abruptly ended with a burst of hyperactivity, mild euphoria, and rapid pressured speech. Two days later he calmed down and seemed coherent, logical, and relevant for the first time since his admission. The remaining 2 weeks of hospitalization were uneventful, and haloperidol was reduced to maintainence levels (5 mg/day).

Four days after discharge, the patient was readmitted in an acute psychotic state after he again used PCP. He was unable to be maintained out of seclusion—despite haloperidol in doses of 100 mg/day—because of grossly inappropriate and unpredictable behavior, which occasionally became hostile and assaultive. He was illogical, with idiosyncratic austistic thought, had visual and auditory hallucinations, and constantly denuded himself. He was maintained on high doses of neuroleptics, and this symptom picture gradually changed over the next 4 weeks, with affective elements coming into prominence. He became excessively hyperactive, with insomnia, grandiose delusional thought, euphoria, and a high-spirited affect that contained a genuinely humorous clowning, imitative aspect. Lithium carbonate was tried during this period, but oral administration was unreliable and serum lithium levels could not be obtained because of the patient's inability to cooperate with the treatment. All medications were stopped and he was given a course of bilateral ECT. He responded dramatically midway through a course of six treatments and lost essentially all of his psychotic symptomatology. He was maintained off medication and observed. After a week and a half he relapsed suddenly, becoming agitated, hyperactive, volatile, and irritable (although generally euphoric), with profuse illogical thought and inappropriate jokes and puns. He was given another short course of ECT and subsequently started on lithium carbonate (1800 mg/day). He again responded dramatically, becoming symptom-free, and was able to cooperate in the administration of lithium therapy.

The patient has been followed now for 8 months. He has continued to cooperate with lithium carbonate therapy. Clinical observation and reports from the family both indicate no recurrence of his psychosis. The patient was able to take a summer job and planned to return to school in the fall.

Received Sept. 5, 1978; accepted Sept. 29, 1978.

Discussion

One great difficulty in the management of this patient's illness was diagnosis. He had developed a severe, prolonged psychosis after PCP abuse that was refractory to high doses of various neuroleptics but responded dramatically to ECT. However, he did not go into remission until lithium carbonate was started. His symptom picture was florid and went through many phases (including catatonia) but eventually appeared to be a severe manic episode that met research criteria proposed by Feighner and associates and Abrams and Taylor (4). Abrams and Taylor (5) have shown that catatonic signs and symptoms are most often a component of an affective illness and should not be equated with a schizophrenic disorder. The pattern of this patient's dramatic response to ECT also resembled that of an affective illness (6). Finally, the patient's lack of residual symptomatology suggests an affective illness.

Slavney and associates (2) retrospectively reviewed post-PCP psychosis and found an association with manic illness but not with schizophrenia. PCP abuse is increasing, and it is important to recognize symptomatic mania as a possible consequence. If these manic episodes are in fact "symptomatic" and causally related to PCP toxicity, one would expect this condition to be most prevalent in adolescents and young adults (in whom one does not usually expect to see an affective illness). Because the reported patients have shown a poor response to neuroleptics, the importance of a correct diagnosis is crucial.

IN MEMORIAM

Edwin F. Gildea
1898–1977

WASHINGTON UNIVERSITY in St. Louis, standing astride the confluence of the Mississippi and Missouri Rivers, has commanded an influential position in directing the currents of American psychiatry. After the second world war psychiatry became a contemplative field, heavily invested in the subjective and individual response of patients and the complex interpretation of motives and behaviors. Many schools burgeoned—sometimes with overlapping, sometimes with diverging viewpoints, but all mainly devoted to the attempt to understand depth psychology. During this time the Washington University Department of Psychiatry flirted with this approach but gradually settled into a strong alliance with biology, a medical view of psychiatric illness, and heavy reliance on reproducible data.

Why did this aberrant development take place in St. Louis? Why did Washington University not follow the streams that were common to most other American medical schools? To a large extent the responsibility and honor belong to Edwin F. Gildea, a person with tolerance and uncommon intelligence, who died on July 19, 1977.

I first met Ed Gildea in July 1950, when I went to St. Louis for a third year of residency training in psychiatry. Dr. Gildea had been there as department head since 1942, having succeeded Dr. John Whitehorn, who had moved to Johns Hopkins. The department at that time was somewhat unstable, with a number of people coming for short periods while they were getting started in private practice and then leaving. Psychoanalysis was heavily represented by a number of people who had clinical appointments and did a good bit of teaching of residents. The psychosomatic service was relatively strong and stable under George Saslow. Electroencephalography and electrophysiological research were conducted by George Ulett. About 1949 a young man had come from Boston to join the department because of Ed Gildea's excellent reputation as a leading biological psychiatrist; that was Eli Robins. A mainstay of the department was Dr. Margaret Gildea, Ed's wife, who combined a very practical attitude about psychiatric treatment with a dynamic viewpoint. Those of us in the residency program considered her a particularly bright, attractive, and sophisticated person.

Ed himself was a large man, with the pinkish complexion that one often sees on the streets of Dublin. He smoked huge pipes that he stuffed with heavily aromatic tobacco. He had originally come from Colorado and still liked the western way of life. It was rumored that frequently when he had to take a train trip he would settle down in the club car with a wide-brimmed hat and pass himself off as a cattle rancher.

He had graduated from Harvard Medical School in 1924, interned at the Boston City Hopsital between 1924 and 1926, and was a resident at the Boston Psychopathic Hospital from 1926 to 1928 in psychiatry and neurology. He also had postgraduate training in neurology and neuropathology between 1928 and 1929 at Harvard. He joined the faculty at Yale University in 1930 and stayed there 12 years until he became the Wallace Renard Professor of Psychiatry and Head of Psychiatry and Neurology at Washington University. He remained in that position from 1942 to 1966, afterwards becoming an emeritus professor.

At all times Ed Gildea relied heavily on data. Prior to going to St. Louis, I had written a paper on a rationale for psychotherapy and anxiety, obsession, and depression. I was particularly proud of the paper because it was almost incomprehensible, something that I thought made me a distant intellectual relative of Harry Stack Sullivan. I presented the paper to Ed Gildea, who read it carefully. He told me to go ahead and publish it and then added something like, "It doesn't seem to have much data in it, does it?" I did publish the paper but in retrospect I believe I should have listened to him more carefully.

Dr. Ed had a quiet, sandy voice and a "homey" attitude, which, however, masked considerable sophistication and erudition. He seemed knowledgeable about everything of importance that had gone on in the field of psychiatry. He had seen hundreds of patients and was an excellent attending man. Residents whom he taught loved to recall his reminiscences about his father, a general practitioner in the west, who used to take care of Teddy Roosevelt when the latter would make trips to the west in the midst of significant mood changes. He also enjoyed telling about his mother, who, he said, was one of the original "anxiety neurotic" patients studied by Mandel Cohen and Paul Dudley White. He said that when the well-to-do ladies of Colorado heard that Dr. White had a new machine (the electrocardiogram) which told all about their heart they rushed to Boston to be worked up. His mother was one of them, and she received the diagnosis of anxiety neurosis. Years after meeting him I asked what had happened to his mother's anxiety neurosis (she was in her mid-90s at that time). He told me, with some amusement, that she still had it. He always did have a feeling for follow-up studies!

In 1952 I left St. Louis for a stint in the Air Force after having spent one year as a faculty member at Washington University. I recall saying to Dr. Ed when I returned in 1954 that I was certainly pleased that I had enough to do, since I had hardly been overworked in 1951–52, my first year on the staff. In fact, I noted that I had spent a good part of the lunch period sleeping on an analytic-type couch that had been provided for me. He seemed pleased that I was working a little harder, did not seem concerned that I had not been particularly productive a couple of years before, and said, "I thought you were thinking all that time."

Drs. Ed and Margaret Gildea did a very good job of raising

morale in the department. Every summer they invited the faculty and residents to their farm in Potosi, Mo. This was usually a hot and buggy occasion but was highly regarded by most concerned; Ed always was amused at the fact that the martini drinkers looked on it as a necessary kind of suffering. Every Christmas the Gildeas also held a cocktail party. In 1950, in addition to personal friends, residents, and faculty, five Nobel prize winners were in attendance. It was the big world.

Ed Gildea was one of the early people to emphasize biochemistry in psychiatry and had countless important publications in this area to his name. It was said that he had carried the available methodology for biochemical investigations in psychiatry as far as it was possible to go at the time. He studied serum proteins and lipid changes in schizophrenic and manic-depressive patients. He did early studies on the thyroid and on ACTH and cortisone in the psychoses; in his later years he wrote an important clinical paper about the differentiation of schizophrenia from schizophreniform psychosis.

It was under Ed Gildea's aegis that the psychiatry service at Barnes Hospital and Washington University became integrated for blacks. What is particularly important is that he supported this integration because he thought it was right, not because he was under any pressure to do so.

What is written above is an attempt to give a picture of Ed Gildea as a person and as a scientist. But his contributions transcend those points. Had it not been for his leadership of the Department of Psychiatry at Washington University, it is doubtful that the department would have developed in the way it did. He showed favoritism toward no one; toward all he expressed a quiet but insistent demand for evidence. What he did was provide a field on which intellectual conflict could occur. While he attempted to keep people from becoming personally injured, it was clear that he enjoyed the give-and-take of different ideas. As time went on, a biological viewpoint emerged more and more strongly. Heavy reliance on hard-nosed clinical diagnosis became apparent, while theorizing, adherence to universal theories, and dynamic interpretation became less evident. Nevertheless, he continued to give the more subjectively oriented psychiatrists opportunities to function and in particular set aside for them the area of child psychiatry. The department became tougher minded as a natural consequence of the vigorous interaction between various factions. As a result Washington University has influenced research and clinical activities and has achieved a unique role in American psychiatry.

In Gray's "Elegy" there is a line, "The paths of glory lead but to the grave." This is true, but to this we should add that in the case of Ed Gildea, the substance may fade but the reflections live on.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, comments on Association activities, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

More on Klinefelter's Syndrome and Affective Illness

SIR: Stanley N. Caroff, M.D. ("Klinefelter's Syndrome and Bipolar Affective Illness: A Case Report," June 1978 issue) was correct in assuming that the second patient reported in our paper (see reference 1) should have been diagnosed as manic-depressive, not only because of the features Dr. Caroff quoted but also because of the patient's grandiose plans. However, the patient had been referred by another psychiatrist, and we did not feel free to comment on the diagnoses, especially since we were primarily interested in the patient's pedophilic propensities. Dr. Caroff mentioned that reports of patients with Klinefelter's syndrome and bipolar illness are rare; I would like to report another such case.

Mr. A, a 49-year-old engineering technician, sought help in August 1970 for irritability, overactivity, crying spells, biparietal headaches, early waking, and worry that had persisted for several months. He had no other psychiatric history. He described frequent clashes with his three adopted children and said his sexual interest had been decreasing for the previous 3–4 years.

He was an only child, and although he was quiet he got along well at school and with friends. He completed 12th grade. He had had several girlfriends but said he had never been at ease with girls. He married at 26 because he thought he should settle down. Neither he nor his wife knew, despite investigations, why they had not been able to have children.

Mr. A had some bronchospasm and very small testes. He was a big man (6′2½″) with long legs, a very broad pelvis, and a short trunk. He spoke loudly and emphatically, swearing often, demanding attention, and showing flight of ideas. He broke into tears when his family was mentioned. These crying spells annoyed him, and his mood would shift from short episodes of apparent sadness to a prevailing anger and irritability. Mr. A had no delusions or hallucinations, a clear sensorium, and intelligence estimated as average (his score on the Wechsler Adult Intelligence Scale 3 years later was 102).

Skull films, EEG, brain scan, and visual fields were all normal. A buccal smear was positive for sex chromatin, and Barr bodies were seen in 20% of cells. The diagnosis was manic-depressive disorder, hypomanic phase, and Mr. A was treated successfully with thioridazine and follow-up clinic visits.

In May 1971 he returned to the hospital complaining of weakness, fatigue, crying, early waking, poor appetite, depressed mood, and thoughts of suicide. He was diagnosed as having manic-depressive disorder, depressed phase, and successfully treated with imipramine. In September 1972 he suffered another depression, which again was successfully treated with imipramine and follow-up visits in the clinic. He was discharged from the clinic as well in June 1974.

Correcting the Underreporting of Father-Son Incest

SIR: I am glad that Katharine N. Dixon, M.D., and associates wrote their paper on "Father-Son Incest: Underreported Psychiatric Problem?" (July 1978 issue). During the last five years, I have come across four cases of father-son incest, three of which were reported by patients who are now adults aged 20–25.

John had been used sexually by his father from the time he was 8 until his father's suicide while psychotic when John was 13. The almost daily activity involved masturbation and fellatio performed upon the boy, whose reaction was a mixture of pleasure, excitement, and shameful disgust. Another patient, Sam, could reveal to his therapist only by letter that his father had used him sexually from the time he was an early adolescent. Dave had sexually molested a 6-year-old boy. He had a history of pedophilic homosexual fantasies and behavior. During early adolescence, Dave had reported on a number of occasions that his physician father had slept with him and had used him sexually. Another patient, a 4-year-old boy, had a history of having his genitals fondled, sucked, and burned by his father, who also required Richard's 7-year-old half-sister to perform sexual acts on Richard.

Two of these patients are from families in upper socioeconomic groups. The adult victims were all quite disturbed and had perversions and borderline personality organizations. Paranoid trends and repetition compulsions to act sexually with either an older man or a male child were also found. The victims' reluctance, even in therapy, to reveal the history of incest was remarkable. Caprio (1, p. 104) found this reluctance in a case of father-son incest that he treated.

The standard texts on sexual perversions and behavior ignore father-son incest. However, in reviewing the literature I have been able to find at least 33 reported cases of father-son incest including 18 cases reported in one German court (2). In one case a physician was sexually active with his three young sons (3).

Now that child abuse is a national issue, I suspect we will hear about more of these cases. However, one aspect of this problem that may be overlooked is the adult victims of this incest, who tend to be reluctant about revealing the pertinent history.

In *Ulysses* James Joyce states that a father and his son

> are sundered by a bodily shame so steadfast that the criminal annals of the world stained with all other incests and bestealities hardly record its breach. Sons with mothers, sires with daughters, lesbic sisters, loves that dare not speak their name, nephews with grandmothers, jailbirds with keyholes, queens with prize bulls. (4, p. 207)

In recent years, the breach of this "bodily shame" is becoming more apparent and recorded.

Contradictions in Survey Results

SIR: I would like to point out some contradictory aspects in the findings reported in "Focused Psychiatric Curriculum Selection: Student, Psychiatrist, and Nonpsychiatrist Physician Expectations" (October 1977 issue) by Warner Johnson, M.D., and associates. Out of a list of 21 commonly taught psychiatric topics, the survey showed the 5 most important topics to be 1) the ability to talk with patients about their personal problems, 2) an understanding of the emotional aspects of the chronically ill or dying patient, 3) familiarity with the dynamics of the doctor-patient relationship, 4) an awareness of when and how to refer a patient to a psychiatrist, and 5) the ability to evaluate a patient's potential for suicidal or destructive behavior or need for psychiatric hospitalization. Among the 5 least important topics to learn, the survey showed that "an understanding of the principles of psychoanalytic theory" is the least important. The contradiction is in how the top 5 topics can be taught and be understood without referring to psychoanalytic concepts, such as defense mechanisms in symptom formation, transference reaction in the doctor-patient relationship, identification in suicides, dependence and regression in chronically ill and dying patients, etc.

The second point is that the ability to do brief psychotherapy as a topic is ranked as sixth from the bottom in importance. Again, this contradicts the choice for a familiarity with the dynamics of the doctor-patient relationship. I tend to believe that the familiarity with the doctor-patient relationship and ability to do psychotherapy are very much interrelated. To carry the argument further, the ability to understand the emotional aspects of patients requires many activities from physicians, and such activities involve the basic quality of being a physician. These activities include listening, giving support, reassurance, and advice, empathic understanding, and even at times confrontation. All these are basic psychotherapeutic interventions. A good doctor-patient relationship is the basis for a good psychotherapeutic relationship. The moment a physician intervenes, be it in giving information, advice, or a prescription, he or she is doing psychotherapy.

I seriously question the validity of these opinions, and would like the authors to clarify these issues.

CHRIS YUNG, M.D.
El Paso, Tex.

Dr. Johnson and Associates Reply

SIR: Dr. Yung raises two interesting points about some apparent contradictions in the findings of the survey. In essence, he asks how dynamic topics such as interviewing skills, the doctor-patient relationship, and others could be selected for teaching, while concepts of psychoanalytic theory would be excluded. We do not have any factual information as to why the survey respondents made their selections but are willing to offer speculations. We suspect that the ranking of topics was based upon which ones were perceived as interesting, needed, or aversive, rather than whether they would constitute a logical sequence for a curriculum. In other words, topics were selected according to what the respondents wanted or did not want to learn. But whatever reasons lay behind their choices, formal course work in psychoanalytic theory consistently received a low priority rating by students, primary care physicians, and psychiatrists alike.

We do not agree with the premise that education in psychoanalytic theory is necessarily a prerequisite for teaching interviewing skills, the doctor-patient relationship, or other dynamic topics. At the University of Southern California School of Medicine, we teach psychodynamic concepts as they are applied to medicine without specific reference to complex speculative theories, and we rarely find the need to introduce technical psychiatric jargon. Psychoanalytic theory, along with mental retardation and behavioral modification, are topics which consistently received a low priority rating by the survey respondents. As we suggested in our article, if these topics are to be taught, it would be well for educators to take into account the low receptivity of students for these topics. Special efforts by the instructor may be needed to make the topics more interesting or relevant, if they are not to be quickly forgotten by the students.

Dr. Yung's second point is concerned with the seeming contradiction in that the survey respondents gave a low rating to learning psychotherapy while ranking an understanding of the dynamics of the doctor-patient relationship as a relatively high-priority item. He raises the question of how one can learn about interventions that are psychotherapeutic and yet exclude teaching about the principles of psychotherapy. Again, we have no hard data on the subject, but we suspect that the respondents saw no such contradiction. Formal instruction in brief psychotherapy would be perceived as

belonging more to the domain of a professional psychotherapist and therefore less as a concern for a primary care physician, while managing the doctor-patient relationship would be something that would be important for all physicians. Furthermore, we feel that it is better to define "psychotherapy" in terms of its being a distinct treatment discipline. Although psychotherapy includes many interventions and methods which are psychotherapeutic, not all that which is psychotherapeutic necessarily is part of psychotherapy. Therefore we feel that the terms cannot be used interchangeably.

We appreciate Dr. Yung's comments and affirm again our position that psychiatric educators must be aware of changing "consumer" preferences with regard to which aspects of psychiatry they are interested in being taught. We feel that it is important to set a priority of teaching topics and also to consider the expectations of the learners for any curriculum that is to be taught.

We welcome further comments on this matter.

Tricyclic Antidepressants, Anxiety, Thromboxane A2, and Dipyridamole

SIR: In their article "Successful Treatment of Severe Anxiety Attacks with Tricyclic Antidepressants: A Potential Mechanism of Action" (July 1978 issue), Kenneth Jobson, M.D., Markku Linnoila, M.D., Ph.D., John Gillam, M.D., and associates suggested that low doses of tricyclic antidepressants were effective in treating anxiety attacks. The plasma levels of drug achieved were probably insufficient to modify amine uptake or to block alpha or beta receptors, and the authors suggested that inhibition of monoamine oxidase might be the relevant mechanism.

I have an alternative suggestion. My group has recently shown that tricyclic antidepressants can inhibit intracellular calcium release in muscle with a threshold of about 1 ng/ml (1). We have shown that benzodiazepines can also block intracellular calcium release at concentrations readily achieved in human plasma (2). The effect is consistent with the idea that the drugs are interfering with the action of a prostaglandin-related substance, thromboxane A2 (TXA2), which seems required for intracellular calcium release (3).

This raises the possibility that anxiety might be related to excess TXA2 formation. If so, then the inhibition of TXA2 synthesis should relieve anxiety. Dipyridamole, an antiplatelet aggregating agent, has actions consistent with inhibition of TXA2 synthesis. I have recently treated two persons who in the past had repeatedly had acute anxiety attacks after stopping smoking. The attacks were so severe that they had always started smoking again. The two patients were given 12.5 mg dipyridamole q.i.d. starting at the time of the last cigarette. No anxiety attacks occurred until the third day, when trial withdrawal of the drug led to panic attacks in both patients 8–10 hours after the last dipyridamole dose. Those attacks were terminated within one hour of the patients' taking dipyridamole again. After three weeks with no smoking dipyridamole was successfully withdrawn from both persons without any resultant panic attacks.

My associates and I have recently provided evidence that oxyheme compounds may enhance TXA2 synthesis (4). In smokers in whom carbon monoxide inactivates 10%–25% of the oxygen-carrying capacity of the blood, this oxyheme stimulation is reduced, but TXA2 levels may be maintained at normal values by other mechanisms. When smoking stops, the removal of carboxyhemoglobin leads to a rebound overproduction of TXA2 and anxiety. This phenomenon could account for the anxiety states that often occur in patients with polycythemia (even before diagnosis) and that in some may be so severe as to deserve an eponymous name, Gaisbock's syndrome.

This proposal that antianxiety and antidepressant agents may act by modifying thromboxane- and prostaglandin-regulated calcium movements opens up a completely new approach to the mechanism of action of these drugs.

Effects of Psychoactive Drugs on Ejaculation

SIR: Psychoactive medications can cause nonerection, nonejaculation, and retrograde ejaculation. Retrograde ejaculation, described by James E. Nininger, M.D., in "Inhibition of Ejaculation by Amitriptyline" (June 1978 issue), is probably the least common. The incidence of these effects is highly idiosyncratic, as Kotin and associates (1) showed in the case of thioridazine. In a considerable but unquantified proportion of patients receiving tricyclics or the MAO inhibitor phenelzine, ejaculation is delayed or inhibited. The threshold for the ejaculatory reflex appears to be raised, since many individuals ejaculate on masturbation but not on intercourse.

The erectile mechanism involves central, parasympathetic, sympathetic, and vascular elements, all of which are potentially altered by tricyclics. It is not usually affected by beta-blocking agents, although one case of apparently pharmacogenic impotence was reported for propranolol (2). Idiosyncrasy in response is therefore difficult to analyze. Much could be learned about erectile physiology by careful history taking.

Delayed ejaculation can be distinguished from retrograde ejaculation by the criteria Nininger used—the sensation of orgasm is absent or much postponed in the former. Whether postponement or nonejaculation occurs will depend on 1) age—nonejaculation in perhaps two of three acts of intercourse is common in men over 50 who have frequent intercourse, and 2) sexual pattern—some men respond to minor stresses (fatigue, infection) with impotence and others with nonejaculation. These apparently consistent intraindividual

patterns should be inquired about in assessments of possible drug effects.

The ejaculatory effects of tricyclics tend to appear early in treatment, before there is increased libido associated with improvement, and to decline with time. Similar effects with phenelzine appear after 4–5 days and disappear rapidly on withdrawal of the drug. The decreased libido reported by Friedman and associates (3) in subjects treated for neurodermatitis with phenelzine is unusual; it may result from delayed or altered ejaculatory sensation. In prostatectomy it is not uncommon for the unprepared patient who experiences alteration of ejaculatory sensation postoperatively to become secondarily impotent because of anxiety over the change. The effects of phenelzine on ejaculation are probably local actions of the drug; they are not synchronous with MAO inhibition.

The most likely site for these effects is preorgasmic glans tumescence. In men who complain of absent or delayed orgasm the glans is flaccid even when erection is complete. In premature ejaculation the glans may enlarge before the corpora begin to fill. A raised threshold for glans enlargement may well be the mechanism involved when tricyclics are beneficial in treating premature orgasm.

Now that erectile physiology can be more freely discussed with patients, it is important for prescribers to collect and report the incidence and precise character of drug effects. Although erectile and ejaculatory deficits may be psychogenic, the mechanics of interference can be demonstrated in an increasing number of cases (4), and the incidental evidence of therapeutic experiments can greatly increase our knowledge of erectile physiology and idiosyncrasy.

"Borderline"—Subtype of Primary Affective Disorder?

SIR: In "Discriminating Features of Borderline Patients" John G. Gunderson, M.D., and Jonathan E. Kolb, M.D. (July 1978 issue) conclude that "borderline patients can be discriminated with high accuracy from matched comparison groups with whom diagnostic confusion is common." The fallacy in their study is that "borderline patients were compared with schizophrenic patients, neurotic depressed patients, and a group of patients with differing diagnoses," whereas contemporary use of the term "borderline" is for patients with bipolar primary affective disorder (1).

A bipolar or mixed primary affective disorder comparison group was not included, perhaps because borderline is primarily an analytic concept (both authors are psychoanalytically oriented) and psychoanalytic theory is not comfortable with the idea of primary affective disorder (2).

This is not to say that the concept of borderline is useless. It is a sophisticated clinical formulation of what is ultimately a subtype of primary affective disorder.

KENNETH NAKDIMEN, M.D.
New York, N.Y.

Drs. Gunderson and Kolb Reply

SIR: Dr. Nakdimen states that borderline patients are a subtype of primary affective disorder. This is an interesting hypothesis for which there is some preliminary evidence in the work of Stone and in the claims for responsivity to MAO inhibitors made by Klein. However, because of contradictory trends suggesting a genetic linkage to chronic schizophrenia and the prevailing clinical wisdom of drug unresponsiveness in this group, Dr. Nakdimen seems unduly bold in his assertion. In any event, Dr. Nakdimen's belief that borderline patients would be difficult to distinguish phenomenologically from patients with primary affective disorder is naïve. The patients in our neurotic depressive group (1) appear to meet Feighner's criteria (2) for primary affective disorder and yet are relatively easy to distinguish descriptively. It would be far easier to distinguish our borderline sample from a comparison group composed of patients with bipolar primary affective disorder. Having said this, we can still agree with the idea that some undetermined fraction of patients with primary affective disorder have a borderline personality organization as outlined by Kernberg (3). The patients with the borderline personality disorder we described are in a narrower category which may find its place in the nosologic system with other forms of personality disorder but is not expected to encompass them. We expect that the most challenging comparison group we could have selected would have been patients with other forms of personality disorder—not primary affective disorder. We did not do this because of the concerns in the psychiatric literature about whether patients diagnosed as borderline could be discriminated from the schizophrenic and neurotic depressive groups which we selected.

It is our belief that diagnosis should depend on more than phenomenologic discriminability—it should depend on external validating criteria. Here our psychoanalytic orientation suggests that a particularly important validating criterion is whether a syndrome has an internal psychological coherence and that the areas to which Dr. Nakdimen refers (i.e., genetics and drug responsivity) have no necessary priority in this respect.

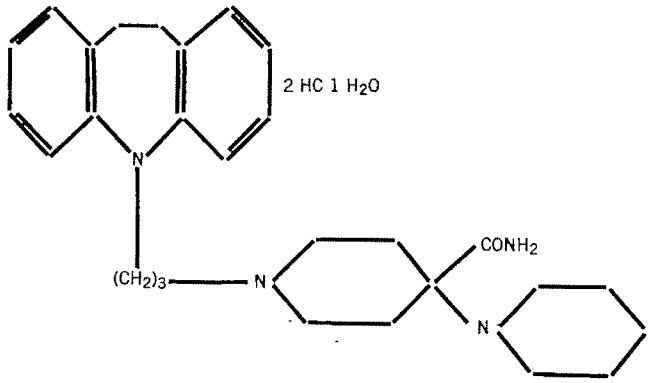
A First-Degree Query

SIR: The paper "Psychiatric Illness in Relatives of Patients with Parkinson's Disease: An Expanded Survey" by Andrew Winokur, M.D., Ph.D., and associates (July 1978 issue) was appreciated. In the paper, the authors stated that "the 25 probands had a total of 113 male and 109 female first-degree relatives," or a total of 222. Neither I nor anyone I have asked can define first-degree relatives in a way to fit the data of almost 9 relatives for each patient unless we assume these families were unusually fecund. I had thought, apparently mistakenly, that first-degree relatives were parents and siblings. It would be helpful to learn which kin the authors include in that term.

HENRY B. BURTON, M.D.
Boone, N.C.

Dr. Winokur Replies



SIR: In response to Dr. Burton's questions concerning the number of relatives of the 25 probands in our study, we obtained data on all of the following: grandparents, parents, siblings, and children aged 18 and over. Only those relatives for whom a reliable history of possible psychopathology was available were included in the final data analysis.

ANDREW WINOKUR, M.D., PH.D.
Philadelphia, Pa.

Corrections

In the August 1978 issue there was an error in figure 2 of "Impact of Neuroleptic Chemotherapies on Schizophrenic Psychoses" by Pierre Deniker, M.D. The corrected figure appears below.

FIGURE 2
Structure of Carpipramine

There was also an error in table 3 of the "1977 Annual Report of the American Board of Psychiatry and Neurology, Inc." in the Official Actions section of the October 1978 issue. In the last column, headed "Foreign Graduates," the second number in the % column should be 50, indicating that 50% of the foreign graduates who took this examination passed.

In the November 1978 issue there was an error in "A Look at Psychiatric Decision Making" by Bruce Roberts, M.D. The first sentence of the second paragraph of the second column on page 1385 should read, "Assuming that we are dealing with the manifestation depressed mood, we see that condition 1 is "Y"; . . . ."

Also in the November 1978 issue there was error in "Prediction of Self-Mutilation in Hospitalized Schizophrenics" by David Shore, M.D., Douglas J. Anderson, M.D., and Neal R. Cutler, M.D. The second paragraph of the Discussion section should read, "Simultaneous with our study three investigators (J.E. Crowder, C.A. Gross, and J.E. Heiser), ..."

The staff regrets these errors.

BOOK REVIEWS

Oneness and Separateness: From Infant to Individual, *by Louise J. Kaplan, Ph.D. New York, N.Y., Simon & Schuster, 1978, 280 pp., $9.95.*

This book is an oasis—both literary and clinical. Dr. Kaplan has produced a combination of poetry and science. Both are apparent in her description of "the beginnings":

> Birth is a rupture of the state of biological oneness of mother and fetus. Mending the rupture is the major task of the mother-newborn couple. During the first month of human life, mother and newborn must come to know each other in a manner that will replace the physical oneness of the womb with psychological oneness, a oneness that is essential to life outside the womb as biological oneness was to life in the womb. (p. 59)

We have become accustomed to and perhaps stultified by the language of texts that profess to be scientific. We have forgotten that a good literary style can be as helpful to the scientist as it can to the art critic.

Clinically, in current books about childhood, we have lost the prospect of an intense and microscopic look at the early months of a child's life. We are so besieged with books describing the child's journey in a longitudinal sense and in a broad family context that we forget the intimacy as well as the intricacies of the beginnings. We are also so buffeted with the pathological (and who can deny it?) that it may be hard to imagine or even visualize true normalcy.

A pupil of Margaret Mahler, Dr. Kaplan has turned her microscope on the intimate and slowly-but-constantly changing relationships between mother and child. Many of these relate to the inevitable biological growth of the child, and many relate to the psychological growth of the mother in compensating for the changes she perceives, accepts, and adapts to in the child. The father is not forgotten, but this book primarily focuses on the small triangle and does not encompass, except in allusion, the larger world outside.

The book does not lack for usable clinical material in the detail. One cannot but be awed by the observations and knowledge represented in this small text. Dr. Kaplan has adopted a most useful device: a series of notes, arranged chapter by chapter, which can be read either before or after the narrative but which leave the actual telling of the changes uncluttered.

The descriptions of life periods are primarily Mahler's: beginnings, limbo, oneness, separation, and constancy. With true simplicity the author describes the extremely new relationships of the second year as the infant carries on the separation process that forces complex responses from parents, particularly from the mother.

Not everyone in the clinical field will accept the author's concept of the "thinking mind," but it is a useful concept to help us understand the particular responses of the child as his or her abilities grow. The thinking mind of the child certainly confronts the parent with a different phenomenon, often much less appreciated than that of the comfortable, warm oneness of the beginnings.

Following the period of growth and separation Dr. Kaplan describes the period of constancy and self-confidence, which gives the child a "sense of contributing in a real way to the real affairs of human life," thus helping the child to put his or her parents in perspective.

With a style peculiarly reminiscent of Nevil Shute, Dr. Kaplan slides from descriptions of the normal to recollections of situations in which the relationship is less than ideal to those in which it is far from ideal: "On the other hand, whenever a child is put in the position of humiliating dependence, his ordinary natural desire to please will be contaminated by fear of aloneness—under conditions of oppression the child may remain a child forever."

Dr. Kaplan closes her brief developmental travelogue with a code describing various ways of living and contrasting some of the difficulties that young mothers face today in cultures that are simpler but not necessarily more satisfying.

Although the style of this book is appealing, the complexity of the text requires careful reading and, at times, rereading. One of the notations on the cover suggests that the book should be especially helpful to "women who are questioning their role of mother as they try to redefine their role of wife." There are no doubt many such women, but those who are struggling with their own concerns about child abuse or who are suffering from economic hazards will not be entirely persuaded by this text.

Perhaps professionals in the field will get more from it. The completeness of the notes makes the entire writing valid. The depth of detail is not only immediately helpful but links together a continuum of knowledge. The theories of how this period is related to later life are made clear. Some will disparage this book for not being keyed to current technological advances. However, Dr. Kaplan provides a clear picture of the biological and psychological basis of existence.

Psychosomatic Families: Anorexia Nervosa in Context, *by Salvador Minuchin, Bernice L. Rosman, and Lester Baker. Cambridge, Mass., Harvard University Press, 1978, 346 pp., $15.00.*

At the end of this interesting, challenging, and important book the authors make the unequivocal statement that "anorexia nervosa is a disease of the child in the family." They reach this conclusion by way of a journey starting with research into the cause of episodes of diabetic acidosis in a group of juvenile diabetics. With the help of a physiological measure—the level of free fatty acids in the blood—the research team was able to track down these episodes to family-induced stress. They then studied these families along with

others, including the families of anorexic patients, and arrived at a formulation of the "psychosomatic family." The anorexic family is considered a psychosomatic family.

The principal tools used by the investigators are "the family task," in which the family is observed while they attempt to reach consensus on a series of set tasks (such as planning a menu), and the "family diagnostic interview," in which a conflict is induced by the therapist between the parents and then the introduction of the anorexic child to detour conflict is observed. The "anorexic family" is characterized by the following behavior patterns: enmeshment, overprotection, rigidity, and, preeminently, conflict avoidance—often through detouring conflict by forcing triangulation of the child into the spouse subsystem. The authors consider all previous theories of anorexia nervosa and methods of treatment of the anorexic patient outmoded. They believe that a systems paradigm using family intervention must supersede the earlier model in the interest of understanding and treating the disease.

The authors used their method of family intervention in 53 families treated over a period of 7 years. Their results were very good both medically and psychosocially in 86% of the cases. Furthermore, the improvements were maintained over a substantial follow-up period. The heart of the book consists of transcripts of the initial therapeutic encounters with four families. Three of these were conducted by Dr. Minuchin and one by Dr. Ronald Leibman. An interesting feature of these interviews is the focal role of a family lunch session during which the anorexic child's eating patterns and the reaction of the family were observed and discussed. In these chapters the reader can observe the lively, engaging, and directive therapeutic technique of the therapists, alternately challenging and ingratiating to the participants.

Have the authors proven their case that family intervention is the preferred method of treatment for anorexia nervosa over all previous and current methods? Their results, although certainly excellent, have been criticized on the grounds that Minuchin and associates were not treating true anorexics, or, if they were, the patients were very young and at an early stage of their illness. Dr. Minuchin takes note of these objections but attributes them to the defensive reaction of linear therapists. Although one cannot read this book objectively without being impressed by the authors' careful approach, the patients do appear to have been young and in a relatively early stage of their illness. The diagnosis of anorexia nervosa includes other more malignant and less tractable conditions; one can acknowledge this without downgrading the method and results reported here.

Scrutiny of the dramatic case study chapters raises questions about the applicability of the authors' theory of the psychosomatic family to all of the cases reported. In fact, the four families seem quite different. A certain amount of straining and Procrustean manipulation is required to fit them into the same framework. The authors' insistence that the theory of conflict avoidance is universally applicable to all of their cases (except one patient who, triumphantly, was found to have an organic cause for her symptoms) is the only really jarring note I found in the book. Even Dr. Minuchin at one point comments that one of the patients, Loretta, seems to have approached intrafamily conflict with a vigor that was certainly not a manifestation of avoidance. It is difficult to accept conflict avoidance as a significant factor among the members of a family who go at each other with the élan observed in Loretta's family.

Rather than ascribing all of the favorable results to the specific maneuvers described to combat the characteristics supposedly definitive of the anorexic family, the authors might have considered an additional and important nonspecific therapeutic factor—the forceful and continuing intervention of an authoritative (and sometimes charismatic) therapist into a disordered family confused and befuddled by their inability to cope with the anorexic behavior of an adolescent child. Such an intervention can be thought of as deflecting and, in a sense, detoxifying the family conflict, thus allowing resolution to take place before the symptoms harden into chronicity and take on a stubborn and resistant life of their own.

The above caveats do not detract from the value of this book and the method of family intervention it describes. This treatment approach appears to be successful for a substantial proportion of cases of anorexia nervosa. Those who use other methods of treatment ought properly to be challenged by these results. They will need to compare them with the results of their own methods.

PAUL CHODOFF, M.D.
Washington, D.C.

Communication and Social Interaction: Clinical and Therapeutic Aspects of Human Behavior, *edited by Peter F. Ostwald, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1977, 337 pp., $24.50.*

Dr. Ostwald, well-known for his own distinguished contributions to the field of human communication over many years, has accomplished a most welcome tour de force in this volume. He has assembled 25 essays from present and former staff members of the Langley Porter Neuropsychiatric Institute, together with a foreword by Lawrence Kolb, a prologue by Jurgen Ruesch, and an epilogue by Gregory Bateson. In a sense, the book is a monument to the Langley Porter group under the leadership of Jurgen Ruesch and Gregory Bateson as well as Enoch Callaway, Leon Epstein, Alexander Simon, Robert Wallerstein, and the late Karl Bowman.

In his magnificent historical survey, Reusch presents the development of the field of human communication and his own significant contributions. Bateson's exposition of the mind-body dilemma and his discussion of his own historical involvement with the theories of logical types, cybernetics, and information theory are superior. Both essays should be required reading for all students in the humanities and the physicochemical, social, and clinical sciences who are grappling for new models of mind with which to understand human behavior.

It is impossible to adequately characterize the 25 essays, which cover a vast spectrum from "Electric Potentials and the Human Brain" by Enoch Callaway to "The Impact of Leadership in the Community" by Chesley Herbert. One can say that each essay has individual excellence and is worth reading. They are grouped into four sections: Basic Elements of Human Communication (essays by Callaway, Gaarder, Ekman and Friesen, Ostwald, Starkweather, and Horowitz), Disturbed Patterns of Communication (essays by Bittner, Raskin, Berblinger, Brodsky, Simon, and Fisher), Communication As a Therapeutic Tool (essays by Langsley, Patterson, Wallerstein, Piner, Motto, Berlin, and Allen), and Communication Adapted to Space, Time, and Social Realities (essays by Flinn, Fiske, Kessler and Glick, Rosow, Lauer, and Herbert).

This alumni roll call is impressive, even startling, in it

scope and guarantees sound scholarship together with an energetic pursuit of innovations. I do not know without trying it out in seminar groups whether this book could serve as a basic text in multidisciplinary studies. I do believe it could be a valuable reference work for all who labor in these difficult fields.

HENRY W. BROSIN, M.D.
Tucson, Ariz.

The World of Emotions: Clinical Studies of Affects and Their Expression, *edited by Charles W. Socarides, M.D. New York, N.Y., International Universities Press, 1977, 612 pp., $24.95.*

Although the centrality of affects in the motivation of human behavior is a core concept in psychoanalysis, the understanding of their role has changed. Formerly considered discharge phenomena, the damming up of which produced symptoms, affects are now viewed as the feelings associated with thoughts that reflect physiological and psychological states, communicate needs, signal danger, influence behavior, affect character development, and stimulate adaptation as well as psychopathology. The articles that Dr. Socarides has collected and on which he comments illustrate the complex interaction of these factors.

The approach in these articles, each of which discusses a different affective state, is essentially clinical. All of the authors stress the importance of the recognition of affects because affect can be denied, repressed, and defended against in a variety of ways due to an individual's fear of being overwhelmed by them or the wish to avoid the pain they generate. The capacity to cope with affects depends on constitutional factors as well as experiences that promote or inhibit maturation.

Searl's article on screaming illustrates the relation of affects to physiology. The unpleasant physiological discharge accompanying the rage expressed in screaming is also an act of aggression. Because the unpleasure associated with the rage is experienced internally, it is felt as an act of aggression against the self. Thus, the hatred against the depriving object is also felt as self-hatred. The subsequent ability to master situations that could stimulate screaming is an important determinant of psychic structure. Zetzel points out that the mastery of traumatic experiences influences the capacity to bear anxiety. Mastery involves the transformation of overwhelming anxiety into signal anxiety. This transformation requires a degree of ego development that is dependent on experiences providing emotional warmth and indicating that human contact is not dangerous and mastery is possible.

The "as if" personalities described by Deutsch have been deprived of these experiences and as a consequence fear affective involvements. Their relationships are distant and superficial. In these as well as other narcissistically wounded people, fear of involvement may result in feelings of emptiness, boredom, and loneliness. Balint and Greenson point out that these states reflect the lack of feedback from others. Attempts to cope with loneliness often result in transient and unsatisfactory relationships based not on love but on narcissistic or sadomasochistic fantasies. The capacity to love, according to Bergmann, is rooted in satisfactory early symbiotic relationships from which the child is allowed to appropriately emancipate himself.

Many of these authors believe that depression early in life is a major factor in the genesis of affective states, which may either be transient or contribute to character structure. In either case, affective states express a view of the relationship and potentially influence it. Rado views melancholia as an attempt at atonement for rage and envy. Bergler relates ingratitude to the persistence of omnipotence as a defense against wounded narcissism, helplessness, and disappointment. Several of the authors feel that wounded narcissism is an important determinant of such states as bitterness, querulousness, smugness, vengeance, arrogance, and jealousy. In each case, the feeling expresses anger at the felt deprivation and is an attempt to obtain reparation. The deprived and narcissistically wounded person may also feel unworthy and may attempt to cope with this by excessive generosity or by responding with undue enthusiasm to situations that promise gratification. Although all of the authors stress the importance of pre-oedipal factors in determining affective states, they also indicate that conflicts and experiences at all levels of psychosexual development contribute to their elaboration.

The dynamics of many of the affective states are similar, but the richness of the clinical material in this book highlights their differences and enhances our understanding of them. This book also provides a stimulus for further study because the articles point out the gaps in our knowledge of the transformation of the physiological into the psychological, the influence of affective states on character formation, and the details that account for the elaboration of similar experiences into different affective states.

REBECCA Z. SOLOMON, M.D.
Hartford, Conn.

The Biochemical Basis of Neuropharmacology, 3rd ed., *by Jack R. Cooper, Ph.D., Floyd E. Bloom, M.D., and Robert H. Roth, Ph.D. New York, N.Y., Oxford University Press, 1978, 322 pp., $13.95; $6.95 (paper).*

The third edition of this textbook provides an up-to-date summary of the biochemical basis of neurophysiology and neuropharmacology. The book is highly readable, the diagrams and illustrations are helpful, and the chapters are appropriate selections from current knowledge of brain biochemistry and pharmacology. Throughout the text the authors strive to evaluate new information and new theories using rigorous scientific standards. Their chapters offer frequent and terse criticisms of studies and hypotheses that were based on imprecise methods or premature conclusions. Gaps in current knowledge are as carefully described as are new discoveries.

A brief introduction explains the book's emphasis on the synapse by noting that the best concepts of neuropharmacological drug action implicate synaptic events. The second chapter outlines the cellular foundations of neuropharmacology and includes a concise summary of the ultrastructure of neurons. This chapter also introduces the important concepts of chemical transmission at the synapse, the brain permeability barrier, and the bioelectrical properties of cells. Perhaps most importantly, the second chapter describes the theoretical and practical approaches used by neurochemists in their attempt to understand neuronal function and synaptic transmitters.

The third chapter contains a brief summary of metabolism in the CNS. The metabolic origins and interrelationships among compounds of neurochemical interest are briefly but clearly presented, and a table summarizes the hereditary

brain diseases that are associated with abnormal cerebral metabolism.

The chapter on receptors, new to the third edition, is a surprisingly succinct account of developments in this rapidly evolving field. The description of the properties of "authentic receptors," the brief but lucid account of the mathematics of receptor kinetics, and the discussion of the phenomenon of "cooperativity" and the concept of "membrane fluidity" will allow the reader to follow future developments in the exciting field of receptor neurochemistry.

The largest sections of the book are devoted to summaries of the current knowledge of putative neurotransmitters. Sections on acetylcholine, the catecholamines, serotonin, the proposed amino acid transmitters (GABA, glycine, glutamic acid, and taurine), prostaglandins, and histamine are balanced reviews of both what is known and what remains to be learned about these neurochemicals. For each proposed neurotransmitter the authors provide lucid discussions of techniques for assay, studies on anatomical localization, and descriptions of anabolic and catabolic enzymes. They also present evidence for the roles of each neurotransmitter in synaptic transmission and, where data exist, in physiology, behavior, and psychopathology. Data on the interaction of active neuropharmacological agents with the synthesis, storage, release, reuptake, or catabolism of these possible transmitters are outlined as part of the description of each compound. Part of a chapter is devoted to the role of the cyclic nucleotides in the general concept of the "second messenger" system. This section contains recent data and descriptions of potential pharmacological interactions with this system. Clearly defined criteria for establishing second messenger mediation should prepare the reader to evaluate new research in this increasingly important area of neurochemistry.

The neuroactive peptides are explored in the other new chapter of the third edition. There has been an explosion of research knowledge on these remarkable substances, and the authors recognize their potential importance. Moreover, they give an accurate and intriguing account of the natural history of research on neuroactive peptides that will guide readers in their review of the already extensive literature in this area.

This book can be strongly recommended as an introductory textbook for graduate and medical students interested in neuropharmacology. Residents in psychiatry and neurology and practicing physicians in these specialties will also find this book an excellent critical review. Owners of the first and second editions will welcome the two additional chapters on receptors and neuropeptides as well as the new information in each chapter. The rapid expansion of knowledge in neuropharmacology will no doubt make some of this book outdated in the near future. I anticipate that future editions of this book will maintain the standard of excellence established by the authors of this monograph.

PHILIP A. BERGER, M.D.
Stanford, Calif.

Psychopolitics, *by Milton Greenblatt, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1978, 268 pp., $18.50.*

Two significant events make the publication of this book particularly timely. The recently completed report of the President's Commission on Mental Health (1) as well as the nationwide concern with government spending should place this book on the required reading list of all mental health professionals. Educators in psychiatry and other mental health disciplines have long sought such a work to assist them with the difficult task of training new people in the field of "psychopolitics." In the past, program directors have learned these important lessons the hard way or have been easily discouraged. Dr. Greenblatt shares his experiences with the reader in a most candid fashion.

The style of this book is appealing and at times even dramatic. It often reads like a novel; one finds himself hurriedly looking to the outcome of the unfolding mystery. Dr. Greenblatt employs the case method to describe his successes and failures and frequently uses examples from his experience in Massachusetts (where he was Commissioner of Mental Health). He applies psychodynamic understanding in many instances.

Dr. Greenblatt is a strong advocate of services and is able to discuss ways of attempting to implement them. After a careful definition of "psychopolitics," he sets out to describe it. There are several provocative subjects covered in the book, such as bureaucracies, consumer groups, patronage, rights of various interested parties, and the use of volunteers.

The subject of the closing of state hospitals and how to phase them out when indicated occupies a great deal of this book. Having gone through a similar experience in my own state, I find the description in the book relevant and familiar. Dr. Greenblatt treats the community mental health center movement fairly and presents both sides of the controversy. He also provides an interesting chapter on the criticisms of psychiatry and discusses positions on drug treatment, ECT, and psychosurgery, dealing with these sensitive subjects fairly and educationally. He also discusses the conflict between what society can afford today and what resources are needed. No doubt this dilemma will be debated on professional as well as fiscal and political fronts in the months to come.

At the close of his book the author presents several points of view on such topics as community mental health centers, the mental health center of tomorrow, resistance to community-based treatment, the minority question, mental health and sexual politics, urbanization and poverty, and psychopolitics and psychiatry. I found the book very readable and even exciting. It should appeal to legislators, bureaucrats, mental health professionals, and critics of the mental health professions.

ALAN M. ELKINS, M.D.
Portland, Me.

Violence and the Family, *edited by J.P. Martin. New York, N.Y., John Wiley & Sons, 1978, 352 pp., $29.95.*

This is one of several British volumes on family violence that resulted from government hearings on the subject. The book is competently authored and contains a blend of criminological data, clinical vignettes, and historical perspectives

However, some chapters are repetitive, and the book is not easily read because it takes on the tone of a reference text with a wide scope.

A chapter on women refugees provides insights into how another culture has attempted to institutionalize something that the United States is just beginning to grapple with. Another chapter points out why the United States has only recently come to look at violence since the political assassinations that have occurred in the last 15 years. Old themes emerge: the failure of the police to intervene in domestic violence and the use of denial by the medical profession.

There is a splendid chapter on training social workers to cope with violent families. It essentially deals with intervention strategies and countertransference issues. There is a very short "note" on men's aid and only a few pages devoted to group therapy with abusing parents. I should like to have seen more on treatment. One essay deals with the need for practical help as opposed to theory and therapy with destitute families. For such people, talking is a luxury. What they require is medical attention, food, money, and the like. I think we often forget this in our community mental health center work.

The editor of this book has an excellent chapter on bureaucratic obstacles to social and medical intervention in the case of family violence. It is refreshing and candid, clinically sound, and useful for all students of social policy in medicine.

JOHN R. LION, M.D.
Baltimore, Md.

The Adoption Triangle: The Effects of the Sealed Record on Adoptees, Birth Parents, and Adoptive Parents, *by Arthur D. Sorosky, M.D., Annette Baran, M.S.W., and Reuben Pannor, M.S.W. Garden City, N.Y., Anchor Press/Doubleday, 1978, 256 pp., $8.95.*

The adoption triangle is illustrated in the Bible by the story of Moses. As a child in Egypt Moses did not know about his Hebrew origin, although his wet nurse was his birth mother. Only as a man was he informed about his heritage; after a struggle of dual identification he finally selected the Hebrew one.

This volume deals with the quest for reunion with lost parents, documented by letters. The letters written by birth parents are fascinating. They indicate resentment, regret, and bitterness as well as interest in the fate of the "lost" child. Letters from the adoptive parents express the other side of the story. There are also letters from the adoptees. For instance, Linda, like Moses, was not told that she was an adopted child. She writes,

> When I was 10 years old I realized that I didn't look like any of the other members of the family, and also wondered why there were no pictures of me as a baby in the family album. During my teens I became preoccupied with the lack of resemblance to my parents. So when I was 18 I ran some blood type tests and determined for myself that I could not possibly be my parents' child.

The search for birth parents is described in detail and easily captures the reader's attention. The time spent on the search varies. In one case it was three years, in another case three weeks. A typical letter gives an idea of the ordeal:

> I found my biological parents within 3 weeks after deciding that I was ready to meet them. I'm a medical student, and I found a sympathetic professor who obtained my birth medical records. It was illegal, but I didn't care, nor did he. My bio-mother had listed a friend and her address as "person to be contacted" and I pursued this route. Using the records office I went through house deeds, found her original one when it was sold and then the next house she bought until I located her.

The description of reunions comprises the most dramatic part of the book. This section illustrates what happens after the search has ended. The majority of reunion experiences reveal a romantic emotional content that is unrivaled in the most imaginative fiction. Ninety percent of the adoptees were satisfied with the outcome of the reunion. Most of these reported a sense of personal fulfillment, resolution of genealogical concerns, and diminished identity conflicts. Eighty-two percent of the birth parents encountered were positive and accepting, and only 10% reacted adversely to the reunion with their relinquished child. In contrast, many of the adoptive parents had difficulty initially in adjusting to the experience. Thirty-six percent of the adoptive parents were cooperative and understanding, 20% were mildly upset, and 10% were quite hurt. In the other cases the adoptive parents had either died or were not told about the reunion in order to spare their feelings.

The authors are very open about their bias—they are in favor of opening the original birth records to adult adoptees—but there are other views as well. For example, Ann Murphy (1) has pointed out that television programs, magazine articles, and angry young people are demanding that old files be opened, that old trusts be violated so that adopted children can discover the identities of their "real" mothers and stage an emotional grand reunion. Ms. Murphy contacted many women who had given up a child for adoption in Georgia and Connecticut and was impressed with the fact that many of these women did not want the reunion. As one of the "real" mothers said, "I'm just a woman who gave birth, I'm not a mother. I contributed the months of pregnancy and the hours of delivery. The woman who raised my child contributed her whole life. She's the real mother—not me."

Clearly, there are two sides to the issue, both worthy of consideration. What makes this volume interesting is not the authors' bias, but the letters from birth parents, adoptive parents, and adoptees. The verbatim account makes the book worth reading.

New Perspectives on Psychotherapy of the Borderline Adult, *edited by James F. Masterson, M.D. New York, N.Y., Brunner/Mazel, 1978, 162 pp., $10.00.*

This collection of papers by Peter Giovacchini, Otto Kernberg, James Masterson, and Harold Searles is rich in clinical offerings. The editor has woven the more formal statements about the borderline adult of each of these four experts with

the informal reactions of the other three contributors. There is, as a result, an intimate, personal characteristic flowing through the book that provides continuity, although there is much lively discontinuity of opinion among the quartet on some points.

In addition to the personal quality that brings the four differing sections of this book together, the authors' knowledge, depth of experience, and differing viewpoints coalesce in such a way that by the time I finished this short book I had a new and fuller view of a complex clinical entity whose very nature defied precise delineation at times. The Masterson group, which initiated and sponsored the conference from which these writings grew, has performed a valuable service in updating our knowledge of theory and treatment of the borderline adult.

My one major suggestion, perhaps too personal to be called a criticism, is that Dr. Kernberg's section, "Contrasting Approaches to the Psychotherapy of Borderline Conditions," should have appeared first instead of third in order in the book. Dr. Kernberg presents a beautifully precise review of the psychoanalytic definitions, concepts, and assumptions that underlie the four authors' contributions. Another minor criticism is that a more accurate title for the book would have been *New Perspectives in Psychoanalytic Psychotherapy of the Borderline Adult* because there are other psychological and psychopharmacological therapies than the psychoanalytic for helping such individuals, regardless of the unanimity among the authors about the psychoanalytic approach.

This book successfully delineates a particular clinical entity and offers a theoretical framework for understanding the psychodynamics of the entity. It also presents differing styles of psychoanalytic therapy using the common denominator of a modified psychoanalytic framework, and thoroughly discusses different and complementary views on the role of the therapist and the importance of countertransference when treating such difficult patients. In the process, the book allows one to review his or her own approaches for helping adults who suffer from the borderline syndrome.

Evaluation of Behavior Therapy: Issues, Evidence, and Research Strategies, *by Alan E. Kazdin and G. Terence Wilson. Cambridge, Mass., Ballinger Publishing Co. (J.B. Lippincott Co.), 1978, 213 pp., $15.50.*

In 1972 Bergin and Strupp wrote *Changing Frontiers in the Science of Psychotherapy* (1). The fundamental thesis of this book was that the question of whether or not psychotherapy is effective was the wrong question at the wrong time and that it was approached with inadequate methodology and insufficient understanding of behavioral and emotional problems. This conclusion led Bergin and Strupp to recommend abandoning large group outcome studies attempting to answer this question in favor of studies smaller in scope answering more specific questions, such as, under what conditions and with what problems do certain well-defined procedures work? However, in the intervening six years these recommendations too often fell on deaf ears, as polemicists and charismatic leaders of various schools of psychotherapy continued the fruitless debate on behavior therapy versus psychoanalysis versus client-centered therapy, etc.

This debate is not continued in *Evaluation of Behavi Therapy*. The purpose of this book is not to extoll the virtu of behavior therapy as yet another school within psychoth apy. The work of these two extremely competent young c nicians and investigators proceeds from the conceptual ba of Bergin and Strupp. Kazdin and Wilson review the existi information on the effectiveness of specific procedures w specific disorders. In a sense it is probably misleading to ti the book *Evaluation of Behavior Therapy* because the cc clusions are relevant to all behavior change procedur based on psychological principles. However, the autho note that a second purpose of their book is to present frankly realistic view of the efficacy of behavior therap These two valuable goals coexist in this book in a manr that detracts slightly from the overall thrust of the work.

Chapter one begins with an overview of behavior thera that is extremely well written and a brief review of conte porary conceptualizations of behavior therapy that are creasingly splintering those within the field. These inclu applied behavior analysis, which grows out of operant tra tions; the neobehavioristic mediational S-R model, whi contains Wolpe's and Eysenck's views of behavior therap social learning theory as espoused most prominently Bandura; and, finally, the newer cognitive behavior therap a collection of procedures often identified with Beck, M honey, and Meichenbaum.

In chapter two the uneasy coexistence of the two ma goals of the book becomes more apparent. After reporting admirably exhaustive review, including tables for easy ref ence, of outcome research comparing "behavior therap with alternative therapies in the areas of neurotic disorde sexual dysfunction and deviance, addictive behaviors, ps chotic disorders, delinquency, childhood disorders, a mental retardation, the authors note that these studies are little worth. Using the well-known study of Sloane and as ciates (2) as an illustration, Kazdin and Wilson state, "'I inadequacies of the data base are for the most part pronounced, and the conceptual model that guided th comparisons sufficiently misguided, that meaningful int pretation is often impossible." Nevertheless, the revi is nicely laid out and the evaluative comments at the end each section allow the reader to determine for himself or h self which studies are useful.

Extending these arguments, the authors correctly nc that recent reviews of psychotherapy outcome literature Luborsky and associates (3) and Smith and Glass (4) cc cluding that, *in general*, all therapies produce essentially t same effect, at least with neurotic patients, are also m leading for the same reasons. With *specific*, well-defined d orders, from phobias through psychotic behaviors and va ous educational applications, and particularly in the rece study comparing cognitive behavior therapy and pharma logical approaches to depression (5), specific, well-defin procedures are superior to alternative treatments.

Although the critical review of outcome studies will pro useful to those desiring this resource, the heart of the bo and the section that advances our science of clinical resear appears in the last two chapters. Chapter three elaborates conceptual and assessment issues making most outcome search problematical at this time, and chapter four lays c detailed guidelines that should shape the direction of search and therapy evaluation for the next 10 years.

This book provides a summary evaluation of the fectiveness of behavioral procedures, but its more import contribution is to invalidate the question of the effectiven of "behavior therapy" or "psychotherapy" and to point

the unique contribution of behavior therapy as a scientifically based approach that asks specific questions about specific techniques and problems.

The Myth of Psychotherapy: Mental Healing as Religion, Rhetoric, and Repression, *by Thomas Szasz. Garden City, N.Y., Anchor Press (Doubleday), 1978, 226 pp., $8.95.*

Thomas Szasz, the outspoken avenger of alleged wrongdoings by the psychiatric establishment, claims in this book that psychotherapy is a combination of religion, rhetoric, and repression. As always, he underscores certain truths about abuses of psychiatric practice and makes a number of good points. He defines psychotherapy as "what two or more people do with, for, and to each other, by means of verbal and nonverbal messages."

In Szasz's view, Freud's definition of conversation as therapy and his definition of those he worked with as patients suffering from mental diseases were false, rhetorical, and self-serving. Szasz sees conversation as religious in origin, with the curing of souls as its goal and rhetoric as its method. He suggests that Freud used the language of science to transform metaphor into accounts of actual phenomena in the brain and that this language attests to Freud's power as a rhetorician rather than to the scientific validity of his constructs. This idea is consonant with current analytic attempts at reworking and/or discarding early metapsychology. Szasz's view of training analysis as an example of coercion by institutional psychoanalysis is under review by some education committees in the United States. His position that Freud was an autocratic leader trying to assure that his marketable product flourished has also been commented on by other writers.

These positions could stimulate useful discussions in professional study groups and analytic seminars. Szasz himself is an able rhetorician with a rich command of psychiatric history. Unfortunately, he is given to extreme positions and overstatements, which in my opinion render his positions meaningless and at times ludicrous. Citing Jones's account of Hoche (who apparently suggested that all analysts should be committed to asylums), Szasz states, "Ironically, many of the criticisms that Hoche leveled against psychoanalysts were well founded, but he overplayed his hand." The same, I suggest, is true of Szasz.

For instance, in a chapter on Mesmer's "medicalization" of magnetism, which Szasz views from a religious and metaphorical perspective, Szasz describes the "so-called hysterical" symptoms of a particular woman as a "case of imitated or pretended blindness." Hysterics, then, do not suffer from real afflictions but pretend to be ill. Szasz says that he does not blame the so-called neurotic, but how else can an accusation of fakery be viewed?

Szasz claims that psychotherapy is "base rhetoric" because it moves the listener to evil. Freud belittles, demeans, and attacks others only to claim that he is attacked by them; he "uses psychoanalysis not to heal but to harm, not to understand but to undermine." In discussing Heinroth, Szasz describes repression concealed as treatment and says that nothing has changed since Heinroth's day. Such accusations overlook subtlety, distinctions among therapists, and the complexities of psychoanalytic treatment.

Szasz also likes to argue freely by analogy. He equates convulsive treatments and leukotomy with psychotherapy and Mesmer's magnetic fluidism with Freud's libido. Szasz would adhere solely to his thesis of metaphor and ban from justifiable investigation all genetic and biochemical studies of brain metabolism. He analogizes Erb's nutritive disturbance of the nervous apparatus with the catecholamine hypothesis and says that ECT is equivalent to chemotherapy and that both are fakery.

Finally, Szasz's continual use of alliteration is a stylistic tic that grates on the reader. In two facing pages, for instance, he talks about "execration and execution," "diagnostic derogation," and "Freud's lexicon of loathing."

Szasz has some important observations to make about the dangers of excess in contemporary psychiatry, including the designation of disparate social and recreational activities as therapy. However, his contributions get lost in his habitual harangue. He reduces and thus dismisses as commonplace the fact that psychotherapy is conversation between "patient and doctor." Attention paid to the content and context of that conversation is precisely what makes psychotherapy a unique and revolutionary contribution. Whether called psychotherapy or "iatrologic," as Szasz suggests, the distinction is ultimately a matter of semantics.

ANDREW P. MORRISON, M.D.
Boston, Mass.

Contemporary Models in Liaison Psychiatry, *edited by Robert A. Faguet, Fawzy I. Fawzy, David K. Wellisch, and Robert O. Pasnau. New York, N.Y., SP Medical & Scientific Books (Spectrum Publications), 1978, 196 pp., $20.00.*

The authors of this book are members of the Department of Psychiatry at the University of California, Los Angeles. They have written 14 chapters covering both common and esoteric problems seen on various UCLA liaison psychiatric services. The case reports given were originally presented in consultation-liaison grand rounds at UCLA School of Medicine in response to a request for psychiatric consultation from the medical-surgical staff of the UCLA Medical Center. Although the chapters are written by different clinicians, there is a pervasive emphasis on a team approach to the various issues discussed. The authors also repeatedly emphasize that the ultimate aim of consultation-liaison psychiatry is the optimal care of the sick by attending to personal and interpersonal issues involving the patient, family, and staff that interfere with medical treatment and management. Furthermore, they explore the varieties of responses to stress and

illness and point out that each patient's reaction is unique and must be understood in a highly personalized fashion.

A listing of the chapter headings gives an overview of the wide variety of topics covered: "The Earliest Intervention: Consultation to the High-Risk Parent and Professional in the Neonatal Intensive Care Unit," "Liaison to Medically-Ill Heroin Addicts: The Mental Health Professional as a Tightrope Walker," "Will I Die? The Child with Life-Threatening Illness," "Life in a Venus-Fly Trap: Psychiatric Liaison to Patients Undergoing Bone Marrow Transplantation," "Infertility and Habitual Abortion: The Search for a Psychological Factor," "Munchausen's Syndrome: The Consultant's Dilemma," "Treating Violence Against Women: The Emergency Room Care of the Rape Victim," "Change Me: The Request for Rhinoplasty," "After Being Turned Inside Out: The Team Approach to the Ostomy Patient," "The Child with Ulcerative Colitis: Play Therapy as a Rehearsal for Surgery," "Psychiatric Aspects of Contraception, Abortion and Sterilization," "The Traction Intolerance Syndrome: Psychiatric Complications of Femoral Fractures in Young Adults," "Endocrines in or and Depression," and "Consultation to Neurology: Brain, Behavior and Patient Care."

It can be seen that the authors cover a wide range of subjects. Their approach is eclectic, and they provide numerous case reports, some of which are vignettes and some reported in detail that reflect the case conference origins of the book. Unfortunately, the writing is inconsistent, the grammar is often poor, and the index is incomplete. Trade names of drugs are used without reference to generic terms. However, the book serves to demonstrate the multidisciplinary character of liaison psychiatry and to emphasize the liaison psychiatrist's unique role of serving the traditional physician's functions of personal, comprehensive, and continuous care through the course of the patient's illness.

This book also accomplishes the objective of blending clinical observations, giving practical guidelines, and producing questions for future research studies. *New Frontiers of Liaison Psychiatry* might have been a better title for this book, which will undoubtedly be referred to by workers in the rapidly expanding field of consultation-liaison psychiatry.

Psychosurgery and the Medical Control of Violence: Autonomy and Deviance, *by Samuel I. Shuman. Detroit, Mich., Wayne State University Press, 1977, 351 pp., $18.50.*

In recent years psychosurgery has received a great deal of attention from philosophers, lawyers, and social scientists—probably more than it deserves in terms of its role in contemporary American psychiatry. It has come to be a symbol for a number of "hot" issues—medicine as a means of social control, competence for informed consent, proxy consent, the relation of therapeutic to experimental procedures, the regulation and control of surgical as opposed to pharmacological treatment, and the significance of involuntary confinement or total institutionalization in the consideration of medical methods of behavior control.

These issues were crystallized by the widely reported "Detroit psychosurgery case," *Kaimowitz v. Department of Mental Health* (1). The Medical Committee for Human Rights brought suit to release a man who had been confined to a state institution for the criminally insane for 18 years and who was to be the subject of a study at the Lafayette Clinic in Detroit on the effect of amygdalotomy on recurrent aggressive outbursts. The committee questioned the law under which the man had been detained, the quality of his informed consent, the scientific validity of the research, and the problem created by research on involuntary detained subjects. The prisoner-subject-patient was released before the trial concluded, but the court held a 15-day trial and commented on many of the basic issues raised. The events leading up to the trial and the opinion of the court have already been described by Ronald Gass (2). They provide the framework for this extended discussion by Samuel Shuman, Professor of Law and Psychiatry at Wayne State University, who represented the Lafayette Clinic and its individual staff physicians in the trial.

Professor Shuman's book is wide-ranging—perhaps too wide-ranging. His topics for consideration include a philosophical discourse on the concept of causation and the medical malpractice dilemma and his preferred solution to it. He touches on many of the critical problems in formulating a policy about psychosurgery, but it is not easy for the reader to extricate these discussions from the text. In addition, there is one important issue that is not discussed at all, psychosurgery itself. There is no discussion of the history, technology, theory, practice, or result of psychosurgery. The book is written by a lawyer and adopts a "black box" approach to psychosurgery, talking about "it" by discussing what various experts have said, what evidence is acceptable and what is not, and what the definition should be but not about the brain or about surgery. Professor Shuman's argumentation is legalistic, and the medically oriented reader may become impatient with his interest in dissecting and destroying the arguments of his opponents and his defending and justifying his judicially rejected position in the Detroit trial rather than examining the available facts directly.

In spite of these difficulties, many critical issues are raised—the relation of abnormal brain tissue to psychosurgery, the concept of causation in brain-mind discussions, the relation of violence control to the restoration of competence, and the question of consent. Many will not agree with Professor Shuman's positions (e.g., a "medical malpractice free market mechanism is likely to be better than . . . any other currently plausible alternative for the regulation of psychosurgery," p. 89), but no one will complain that he hides his personal prejudices. The book will reward the reader with significant and relevant discussions of social, legal, and political aspects of psychosurgery, but only if the reader survives lengthy passages on Wittgenstein, evolution, and the medical model.

Model Law on Confidentiality of Health and Social Service Records

OFFICIAL ACTIONS

Model Law on Confidentiality of Health and Social Service Records

This document was approved by the Board of Trustees at its September 1977 meeting and by the Assembly Executive Committee at its February 1978 meeting. It was prepared by the Task Force on Confidentiality of Children's and Adolescents' Clinical Records[1] and the Committee on Confidentiality.[2]

1. *Scope:*

All confidential information is subject to the provisions of this Act. Except as hereinafter provided, or otherwise specifically required by federal, state or local law, no person shall, without the authorization of the patient/client or his/her authorized representative:

(a) Disclose or transmit any confidential information together with a patient/client identifier to any person, or
(b) Disclose or transmit a patient/client identifier to any person, or
(c) Disclose or transmit confidential information if the person disclosing or transmitting it has reason to believe that the recipient may have a patient/client identifier for such information.

2. *Definitions As Used in This Act:*

(a) "Confidential information" means:
  (i) The fact that a person is or has been a patient/client;
  (ii) Information transmitted in confidence between the patient/client and service provider in the course of service provision;
  (iii) Information relating to diagnosis, facts necessary to the provision of services, or treatment, transmitted in confidence between members of the patient/client's family and the service provider;
  (iv) Information relating to diagnosis, facts necessary to the provision of service, or treatment, transmitted between any of the persons specified in (a) (ii) and (iii) above, and persons who participate in the accomplishment of the objectives of diagnosis, fact-finding, or service under the supervision of, or in cooperation with, the service provider;
  (v) Any diagnosis or opinions formed by the service provider regarding the patient/client's physical, mental or emotional condition;
  (vi) Any advice, instructions or prescriptions issued by the service provider in the course of diagnosis, treatment, or provision of other service;
  (vii) Any summary, resumé or characterization of the substance, or any part of the information described in sub-sections (f), (i) through (v) of this section 2; and
  (viii) Any record, recording, or notation of information described in subsection (f), (i) through (vi) of this section 2, in whatever form and by whatever means recorded or noted.
  (ix) Personal information governed by the School Student Records Act is hereby excluded from the application of this statute.
(b) "Patient/client" means a person who consults, is examined, interviewed, treated, or is otherwise served to some extent by a service provider, or a clinical researcher, as hereinafter defined, with regard to a medical, mental, or emotional condition or social deprivation or dysfunction.
(c) "Patient/client identifier" means:
  (i) The patient/client's name or other descriptive data from which a person well acquainted with the client might, with reasonable certainty, recognize such patient/client as the described person, or
  (ii) A code, number, or other means to be used to match the patient/client with certain confidential information regarding him/her.
(d) "Authorized representative" means:
  (i) A person empowered by the patient/client to assert or to waive the confidentiality, or to disclose or consent to the disclosure of confidential information, as established by this Act. Such person shall not, except by explicit authorization, be empowered to waive confidentiality or to disclose or consent to the disclosure of, confidential information;
  (ii) If the patient/client is incompetent to assert or waive his rights hereunder, or is in an apparently life threatening or emergency situation, a guardian or conservator, except that pending appointment of such guardian or conservator, the nearest avail-

[1]The Task Force on Confidentiality of Children's and Adolescents' Clinical Records (1976–1977) included Frank Rafferty, M.D., chairperson, John Looney, M.D., Herbert Sacks, M.D., and Lenore Petty, M.D., Falk Fellow. Of Counsel: Sandra Nye, J.D., M.S.W.

[2]The Committee on Confidentiality (1976–1977) included Jerome Beigler, M.D., chairperson, Ben Bursten, M.D., Maurice Grossman, M.D., Alan McLean, M.D., Don Mosher, M.D., Herbert Sacks, M.D., Hugo Van Dooren, M.D., and Robert Friedman, M.D., Falk Fellow. Of Counsel: Sandra Nye, J.D., M.S.W.

able relative of such patient/client may maintain or waive the confidentiality;
(iii) If the patient/client is deceased, his personal representative or next of kin or
(iv) If the patient/client is less than twelve (12) years of age, his parent or other custodian or guardian.

(e) "Diagnosis, fact-finding, or provision of service" includes observations made for purposes of same and all efforts to prevent, ameliorate, or otherwise overcome the effects of medical, mental or emotional disorders or social deprivation or dysfunction.

(f) "In confidence" means, private disclosures made or intended to be made, so far as the discloser is aware, to no other persons except
(i) The intended recipient;
(ii) Those who are present to further the interest of the patient/client in consultation, examination or interview, diagnosis, treatment, or other service provided;
(iii) Those to whom disclosure is reasonably necessary for the transmission of the information or the accomplishment of diagnosis or treatment, including members of a therapy group of which the patient/client is a participant, and members of the client's family; supervisors or other persons participating in consultation, examination or interview, diagnosis, or treatment, or other service provided under the direction of the provider; third-party payers; and
(iv) Persons reasonably believed to be engaged in good faith in training programs relevant to the activities of the service provided.

(g) "Person" means any natural person, corporation, association, partnership, and any state, local or federal government, or any agency or other part thereof, including a court.

(h) "Service provider" means any person authorized by statute to provide medical, psychological, psychotherapeutic, psychoanalytic, child welfare and/or other social services; any person reasonably necessary for evaluation, diagnosis, consultation, treatment, or care under the supervision of the provider; and, any person reasonably believed by the client to be so authorized or engaged.

3. *Authorized Disclosures:*

(a) Consent may be given by a patient/client who is twelve (12) years of age or over or by his authorized representative, for the transmission or disclosure of confidential information. Such consent shall be effective only if it is in writing and signed, and also specifies the nature and content of the information to be disclosed, to what person such information may be transmitted or disclosed, and to what use the transmitted or disclosed information may be put. Such specifications shall constitute the limits of the authorization. Every person requesting such authorization shall inform the patient/client or authorized representative that refusal to give such consent will in no way jeopardize his right to obtain present or future service, except where and to the extent disclosure is necessary for service to said patient/client, or for the substantiation of a claim for payment from a person other than the patient/client. The patient/client, or his authorized representative, may withdraw any such consent at any time in writing transmitted to and received by the person authorized to receive such confidential information. Upon receipt of such withdrawal, the person previously authorized to receive said information shall exercise reasonable care in promptly notifying all persons who had previously transmitted information on the basis of said consent, or who might reasonably be expected to do so in the future, that the prior consent has been withdrawn. If consent had been obtained by a person other than the person thereby authorized to receive said information, the person who obtained said consent shall, upon request, promptly, and in the exercise of reasonable care, assist the patient/client in ascertaining the correct name and address to which the withdrawal should be sent. Withdrawal of such consent shall have no effect upon disclosures made prior thereto.

(b) If the patient/client is under twelve (12) years of age or incompetent, consent may be given for the transmission or disclosure of confidential information by the patient/client's authorized representative.

4. *Disclosures Without Authorization:*

Consent from the patient/client shall not be required for the disclosure or transmission of confidential information in the following situations, as specifically limited:

(a) *Within the service-providing facility:* Confidential information may be disclosed to other individuals employed by the service provider, and to officially designated auditors and surveyors for accreditation, when and to the extent to which the performance of their duties in employment, audit or accreditation requires that they have access to such information. For purposes of this subsection (a), (i) persons engaged in good faith in training programs at a service providing facility and their clinical supervisors are to be considered as being employed by the service provider and may have access to such records and information to the extent reasonably required in their training and duties, but, (ii) individuals employed by the service provider or audit or who are involved in financial audit, preparation of bills or who are otherwise engaged in the collection of charges for services to a patient/client shall not, by virtue thereof alone, have access to confidential records and information, except with respect to names, addresses, and other information essential to the preparation and submission of bills and claims for payment of charges for services to a patient/client.

(b) *Clinical supervisors or trainers not employed by the service-providing facility:* Confidential information may be disclosed to supervising or training clinicians by service providers who are in training or supervision under a clinician or bona fide training program, whether or not such supervising clinicians are employed by or affiliated with the service-providing facility. For purposes of this subsection (b), the clinical supervisor or trainer receiving such confidential information shall bear the same position and responsibility with regard to the protection thereof as the service provider.

(c) *Protection from serious injury or disease; The Abused and Neglected Child Reporting Act:* Confidential information may be disclosed, (i) in accordance with the provisions of the Abused and Neglected Child Reporting Act; and (ii), when the statute creating a legislative commission delegates authority to study the needs of minors or incompetents, and to promote services for

the protection of the rights and interest of minors or incompetent persons who are in need of, or provided with medical, social and mental health services; subject, however, to guidelines established by the director of the agency providing the service with respect to the validity of the request for material and to the proper precaution as to its confidentiality and use; (iii) when and to the extent a treating or diagnosing service provider, in his sole discretion, determines that such disclosure is necessary to initiate or continue civil commitment proceedings under the laws of this state or to otherwise protect the patient/client or other person against a clear, imminent risk of serious physical or mental injury or disease or death being inflicted upon the patient/client, or by the patient/client on himself or another; and (iv) when and to the extent such is in the sole discretion of the treating or diagnosing clinician, necessary to the provision of emergency medical care to a patient/client who is unable to assert or waive his rights hereunder and there is no relative or other third party available to give consent. Any person, institution, or agency, under this Act, participating in good faith in the making of a report under the Abused and Neglected Child Reporting Act, or in the disclosure of confidential information otherwise in accordance with this provision, shall have immunity from any liability, civil, criminal or otherwise, that might result by reason of such action.

(d) *Billing and claims:* Information supplied by a service provider to persons involved in the billing for, or collection of, charges for services, shall be limited to names, addresses, dates on which services were performed, and the amount of charges for such services, and shall not otherwise indicate the nature of the conditions for which services were provided. In the event of a claim in any civil action for payment for services, no other confidential information except names, addresses, the dates on which services were rendered, and the amount of charges for such services shall be disclosed in pleadings and motions, except to the extent necessary (i) to respond to a motion of the client for greater specificity, or (ii) to dispute a defense or counterclaim.

(e) *Patient/client-litigant exception:* Except as provided in paragraph (ii) of this subsection (e)

(i) Confidential information may be disclosed in a civil or administrative proceeding in which the client introduces his physical, mental or emotional condition or any aspect of his diagnosis or treatment for such a condition as an element of his claim or defense if and only to the extent the court in which the proceedings have been brought, or, in the case of an administrative proceeding, the court to which an appeal or other action for review of an administrative determination may be taken, finds, after *in camera* examination of testimony or other evidence, that it is relevant, probative, not unduly prejudicial or inflammatory, and otherwise clearly admissible; that other satisfactory evidence, such as the results of a present examination of the patient/client by an examining clinician other than the service provider, or stipulations of fact between the parties, are demonstrably unsatisfactory as evidence of the facts sought to be established by such evidence; and that disclosure is more important to the interests of substantial justice than protection from injury to the provider-patient/client relationship or to the patient/client or others whom disclosure is likely to harm. No confidential communication between a service provider and a patient/client shall be deemed relevant for purposes of this sub-section, except the fact of treatment, the cost of treatment and the ultimate diagnosis unless the party seeking disclosure of the communication clearly establishes in the trial court a compelling need for its production.

(ii) This subsection (e) shall not apply to preclude the assertion of the confidentiality privilege as to confidential information disclosed in the course of any treatment of an abnormal mental or emotional condition

(a) In any action brought or defended under the Divorce Act, or

(b) In any action for damages for pain and suffering that does not include a claim for the treatment of such abnormal mental or emotional condition.

(iii) Confidential information or records may be disclosed in a civil proceeding after the patient/client's death when the patient/client's physical or mental condition has been introduced as an element of a claim or defense by any party claiming or defending through or as a beneficiary of the patient/client, provided the court finds, after *in camera* examination of the evidence, that it is relevant, probative, and otherwise clearly admissible; that other satisfactory evidence, including stipulations of fact between the parties, is not available regarding the fact sought to be established by such evidence; and that disclosure is more important to the interests of substantial justice than protection from any injury which disclosure is likely to cause.

(iv) In the event of a claim made or an action filed by a patient/client, or, following the patient/client's death, by any party claiming as a beneficiary of the patient/client, for injury caused in the course of diagnosis or treatment of said patient/client, the service provider and other persons whose actions are alleged to have been the cause of injury may disclose pertinent confidential information to an attorney or attorneys engaged to render advice about and to provide representation in connection with such matter and to persons working under the supervision of such attorney or attorneys, and may testify as to the said information in any judicial or discovery proceeding for the purpose of preparing and presenting a defense against such claim or action.

(f) *Court-ordered examination:* Communications made to or diagnoses and opinions made by a service provider in the course of examination ordered by a court for good cause shown may, if otherwise relevant and admissible, be disclosed in a judicial or administrative proceeding in which the patient/client is a party or in appropriate pretrial proceedings, provided such court has found that the patient/client has been as adequately and as effectively as possible informed before submitting to such examination that such communications, diagnoses and opinions would not be considered confidential or privileged. Such communications,

diagnoses and opinions shall be admissible only on issues germane to the said proceedings and involving the patient/client's physical or mental condition.

5. *Waiver:*

(a) Particular items of confidential information may be disclosed in judicial proceedings if the court in which the proceedings have been brought finds that the information is relevant and otherwise admissible and that the patient/client or his authorized representative has, without coercion, knowingly waived confidentiality by disclosing, or consenting to disclosure of, the substance of such particular information. In the case of an administrative proceeding, prior to disclosure of confidential information, any dispute as to the issue of waiver of confidentiality shall be referred for determination to the court to which an appeal from the administrative ruling may be taken.

(b) Disclosures that are privileged, disclosures made in the course of obtaining payment for treatment and related services, and disclosures made in the interest of accomplishing a purpose for which the psychotherapist was consulted are not waivers of confidentiality.

(c) For purposes of this section 5, failure by the patient/client or his authorized representative to assert the confidentiality of information in any proceeding in which he has the legal standing and opportunity to do so shall be deemed a consent.

6. *Rulings on Claims of Confidentiality:*

(a) In a ruling on an assertion of confidentiality to prevent disclosure in judicial or administrative proceedings, the court may not require disclosure of information asserted to be confidential under the Act in order to rule on such assertion.

(b) When neither the patient/client nor his authorized representative are parties to an administrative or judicial proceeding or they otherwise lack the opportunity to assert confidentiality, (i) any person asked in administrative or judicial proceedings to disclose confidential information may assert its confidentiality; and, (ii) the presiding officer on his own motion or the motion of any party shall exclude such information. Such presiding officer may not exclude information under this section 6 if, (i) he is otherwise instructed by the client or his authorized representative to permit disclosure; or, (ii) the proponent of the evidence establishes that there is no person authorized to assert confidentiality in existence.

(c) Whenever confidentiality is asserted under this Act in a judicial or administrative proceeding, the party opposing such assertion shall have both the burden of going forward with evidence and the burden of proof with regard to issues of whether confidentiality has been waived and whether any relevant transmissions of information were not made in confidence.

(d) No person shall be held in contempt for failure to disclose confidential information unless he has failed to comply with a court order, a legislative subpoena or an order of an administrative hearing that he disclose such information.

7. *Prescriptions:*

Nothing in this Act shall be construed as limiting or interfering with state and federal regulation and monitoring of the handling and dispensing of prescription drugs; otherwise, however, prescriptions for drugs shall be considered confidential information and subject to the provision of this Act.

8. *Research:*

Persons engaged in research may have access to confidential information that identifies the patient/client where needed for such research, provided no records thereof shall be removed from the service-providing facility that prepared them. Data that do not identify patient/clients or coded data may be removed from a service-providing facility provided the key to such code shall remain on the premises of the facility and no copies thereof are removed. Where the person engaged in research is to have access to confidential information, the research plan first shall be submitted to, and approved by, an appropriate Research Review Committee and by the director of the service-providing facility or his designee. The service-providing facility, together with the person doing the research, shall be responsible for the preservation of the anonymity of the patient/clients and shall not disseminate data that identify a patient/client except as provided by this Act.

9. *Mandatory Cautions:*

(a) All nonoral disclosures of confidential information shall bear the following statement: "The protection of the confidentiality of information contained herein is required under (chapter) of laws of the State of ( ) which provides for damages and penalties for violations. This material shall not be transmitted to anyone without consent or other authorization as provided in the aforementioned statute." A copy of the pertinent consent form specifying to whom and for what specific use such communication or record is disclosed or transmitted, or a statement setting forth any other statutory authorization for disclosure or transmittal and limitations imposed thereon, shall accompany all such nonoral disclosures. In cases of oral disclosure, the person disclosing confidential information shall inform the recipient that such information is confidential under the laws of this state.

(b) Service providers shall ensure that all persons in their employ or under their supervision are aware of their responsibilities to maintain the confidentiality of information protected by this Act and of the existence of penalties and civil liabilities for violation of this Act.

10. *Civil Remedies and Criminal Penalties:*

(a) Any person aggrieved by a violation of this Act may petition the court of common pleas for the county in which he or the alleged violator resides or in which such violation occurred, for appropriate relief, including temporary and permanent injunctions, and such petition shall be first priority with respect to assignment for trial. Such aggrieved person may also prove a cause of action for general or special damages, or both, and, in cases of willful or grossly negligent violations, punitive damages.

(b) A willful or grossly negligent violation of this Act shall be punishable as a Class C misdemeanor. For purposes of this section, in cases of willful disclosure of confidential information, each such disclosure of information pertaining to any one person shall constitute a separate violation.

11. *Employee Discipline:*

(a) Any state, county or local government employee and any employee of a service-providing facility operated under contract to a state, county or local government or department or agency thereof, who repeatedly, willfully or through gross negligence violates this Act, shall be dismissed from employment, or, in the case of mitigating circumstances deemed adequate by the employer, appropriately disciplined and transferred to a position, if available and otherwise suitable, outside a service-providing facility and involving no access to confidential information.

(b) Negligent, nonrepetitive violations of this Act shall render such employees subject to appropriate disciplinary action.

(c) In the course of any disciplinary or dismissal actions against such employees, confidential information shall not be used except to the extent necessary to comply with principles of fair notice and hearing, and patient/client identifiers shall be removed from any such information prior to its use in such proceedings.

(d) All contracts between private persons and any state, county or local government or department or agency thereof involving access by such private persons or their employees, representatives, agents or subcontractors shall include a provision setting forth requirements of this section. Failure to include this clause in any such contract shall not limit the operation of this section.

12. *Patient/Client Access to Information:*

(a) Except as provided in (c) and (d) of this section 12, upon request of a patient/client, a service provider shall, within thirty days following the request, allow the patient/client access to his service record.

(b) The service provider shall establish procedures that: 1) allow a person to purchase copies of his record at a reasonable cost, not exceeding the actual cost of duplication to the service provider; 2) allow a person to contest the accuracy, completeness or relevancy of the record content; 3) allow information contained therein to be corrected on request of the person when the service provider concurs in the proposed correction; 4) allow a person who believes that the service provider maintains inaccurate or incomplete information concerning him to add a statement to the record setting forth what he believes to be an accurate or complete version of those personal data. Such a statement shall become a permanent part of the service provider's personal data system, and shall be disclosed to any individual, agency or organization to which the disputed personal data are disclosed.

(c) If a service provider determines that disclosure to a person of medical, psychiatric or psychological data concerning him would be detrimental to that person, or that nondisclosure to a person of personal data concerning him is otherwise required by law, the service provider may refuse to disclose those personal data, and shall refuse disclosure where required by law. In either case, the service provider shall advise that person of his right to appoint another clinician of his own choice as "clinical mediator" to have access to the record. The "clinical mediator" may, upon review of the record, disclose the record to the person, offer to interpret the contents of the record to the person, or may refuse to disclose. If the "clinical mediator" determines against disclosure and the person is unwilling to accept an interpretation of his record, the service provider shall advise the person of his right to seek judicial relief.

(d) If disclosure of personal data is refused by a service provider under this section 12, the person aggrieved thereby may, within 30 days of such refusal, petition the court of common pleas for the county or judicial district in which he resides or in which the service provider resides or practices, for an order requiring the service provider to disclose the personal data. The court, after hearing and an *in camera* review of the personal data in question, shall issue the order requested unless it determines that such disclosure would be detrimental to the person or is otherwise prohibited by law, or may alternatively authorize disclosure to a designated clinician or attorney.

(e) If the person is under 12 years of age, his parent or other custodian shall have the rights set forth in this section 12 on behalf of that person. Further, if the person, in consequence of physical or mental incapacity, shall have been placed under guardianship, his guardian shall have the same rights set forth in this section 12 on behalf of that person.

13. *Records and Information Pertaining to Minors:*

(a) All confidential information pertaining to the provision of health and social services to a minor shall be deemed confidential, and no disclosure of such information shall be made to the child's parent or any other person, except:

(i) If a minor who is twelve (12) years of age or older consents in writing;

(ii) As provided by sections 4 and 12 (c) hereof;

(iii) If the service provider obtains information that he or she believes requires action to prevent serious harm to the minor or another person, he or she may disclose that information to the child's parent, guardian or legal custodian, or as appropriate under the provisions of the Abused and Neglected Child Reporting Act;

(iv) All records shall be available to the child's counsel of record and professional and paraprofessional persons associated with the child's counsel and to staff members of the Juvenile Court.

14. *Personal Notes: Special Limitations on Disclosure:*

(a) A service provider is not required to but may, to the extent he or she determines it necessary and appropriate, keep personal notes regarding a patient/client wherein he or she may record:

(i) Sensitive information disclosed to him or her in confidence by other persons on condition that such information would never be disclosed to the patient/client or other persons;

(ii) Sensitive information disclosed to him or her by the patient/client that would be injurious to the patient/client's relationships to other persons; and

(iii) The service provider's speculations, impressions, hunches and reminders.

(b) Such personal notes are the work product and personal property of the service provider and shall not be subject to discovery in any judicial, administrative or legislative proceeding or any proceeding preliminary thereto.

15. *Group Health and Life Insurance:*

No person shall demand or request that information as to medical and mental health history, condition and treatment on group health and group life insurance applications, questionnaires and claim forms or any copy thereof or information therefrom, be submitted to an insurance company regarding the insurance coverage of a resident of this state, (a) to or through any member or representative of the group, or (b) to or through the employer or any representative or agent of the employer of the persons covered by such policy, but only directly from the insured or covered persons or their designees and providers of covered health care services or their designees. Insurance companies with group policies covering persons residing in this state and the representatives and agents of such companies, in accordance with rules and regulations to be promulgated by the Director of Insurance, shall, within 120 days from the effective date of this Act (a) take measures to advise group members, employers of group members and representatives and agents of such employers involved in the administration of such policies of the requirements of this section; (b) cause notices regarding this section to be printed prominently on all newly issued or renewal policies, on printed materials intended to be provided to group members and their employers regarding such policies and on all applications, questionnaires, claims and similar forms to be submitted by or on behalf of covered persons and by persons providing covered health care services. For purposes of this section, covered health care services shall include diagnostic and evaluative services. This section shall not apply to applications for life insurance benefit payments.

16. *Health and Life Insurance: Prohibition on Requirement of Consent to Disclosure by Insurance Company to Others:*

No insurance company or any employee, representative or agent thereof shall require of any person residing in this state as a condition of the issuance, continuation, renewal or reinstatement of life, health, accident, medical, hospitalization or similar insurance policy or as a condition of paying any benefits thereunder that an applicant, insured or covered person, or any person acting in his behalf, authorize or agree to authorize such insurance company to disclose or re-disclose confidential information with patient/client identifiers to persons other than itself. Advice that no such requirement may lawfully be imposed must be given in conjunction with any request for such authorization.

17. *State, County and Local Information Systems:*

(a) *Official inspections:* Nothing in this Act shall be construed as prohibiting any state, county or local government official from performing any audits, investigations or inspections of health or social service facilities in the state as required or authorized by law, *provided* that the performance of such duties shall not entail removal from any such facility of any confidential information with client identifiers or any codes or keys to electronically processed information.

(b) *Statistical reports:* Nothing in this Act shall be construed as prohibiting the issuance of statistical reports and similar anonymous data regarding the operations of health or social service facilities.

(c) *Electronic data processing:*

(i) No electronically processed data of confidential information with patient/client identifiers shall be recorded on equipment outside a mental health facility except in accordance with this section.

(ii) Confidential information regarding current patient/clients may be recorded on electronic data-processing equipment outside a mental health facility only if:

1. Such information is encoded by means that make it impossible for persons other than data-processing personnel within such facility to discern the identity of individual patient/clients;

2. The encoding means or devices by which a patient/client can be identified are delivered, within 60 days after a client is discharged or otherwise ceases to participate in diagnosis or treatment, by data-processing personnel within such facility to a person or persons under the direct supervision of the facility director, which person or persons are strictly denied access to the electronic data-processing equipment and are responsible for the safekeeping of such encoding means or devices and the denial of access thereto to all persons except as provided in subsection (iii) of this section 17;

3. The encoding means or devices by which a former patient/client can be identified may be returned to data-processing personnel for purposes of reactivating access to confidential information stored on electronic data-processing equipment when and only when, (1) the patient/client to which such information pertains has reentered diagnosis or treatment at such facility, or (2) a request for confidential information that may be honored under the provisions of this Act has been received; and

4. No later than 5 years after a patient/client has been discharged or has otherwise ceased to receive services at such facility, or in the case of a minor receiving service that was terminated during his minority, no later than 5 years after attaining his majority, either said encoding means or devices pertaining to such patient/client shall be destroyed, or, (2) all electronically processed data pertaining to such patient/client shall be returned to data personnel at such facility. Those facilities planning long-term epidemiological research may request under the research provisions of this statute special informed consent from the patient/client or authorized representative to maintain the patient/client's records for an extended period of time. Treatment may not be denied for failure to consent. The patient/client may at any time cancel consent without prejudice.

(iii) Such encoding means or devices may be disclosed (aa) to the extent necessary for auditors regularly employed by the state to inspect electronic data equipment to ensure strict and complete compliance with this Act, *provided* that such inspections shall not involve the removal of such encoded means and devices, or copies or other reproductions thereof from a mental health facility, (bb) or to the extent required for a fair hearing in connection with the dismissal of an employee charged with violating this Act, and (cc) to the extent necessary for use in a civil or criminal action arising out of violations of this Act.

(d) *Indigency investigations:* Any agency of state, county or local government charged with responsibility to investigate or audit claims of indigency, hardship or sim-

ilar status whereby individuals may receive health or social services without charge or on the basis of reduced charges, shall maintain the confidentiality of the patient/clients in the conduct of such investigations or audits and, upon the completion thereof, shall forward a report to the facility or agency for which prepared and shall keep no record of such investigation by which any patient/client can be identified.

18. *Disclosures Required in Federally Funded Programs:*

(a) Confidential information may be disclosed to federal departments and agencies to the extent required under federal law to obtain reimbursement for diagnosis, treatment and other social services under federally funded programs for review and audit that are a requisite for participation in federally funded programs.

(b) Any organization or agency designated under federal law to perform such reviews or audits of the cases of patient/clients who are residents of this state shall maintain the confidentiality of confidential information, shall not disclose confidential information except to the extent required by federal law, and shall destroy the means by which patient/clients can be identified in such information and records containing such information at the earliest opportunity consistent with the requirements of federal law.

(c) To ensure that confidential information regarding citizens and residents of this state is afforded maximum protection consistent with the provisions of this Act, the directors of each state code department delivering health or social services shall promulgate regulations that specify the minimum information required pursuant to subsections (a) and (b) of this section 18 and disclosures in excess thereof shall constitute violations of this Act. In the event a demand for confidential information in excess of that provided for in such regulations is made on any health or social service provider in this state upon pain of disallowance of reimbursement or other benefits, such provider shall immediately refer the matter to the director of the appropriate state code department or his designee, who shall, on behalf of such provider, attempt a resolution of the matter either by negotiation or appropriate court action, or by authorizing said provider to disclose if he determines that disclosure is required by federal law. Disclosures pursuant to the preceding sentence shall not constitute violations of this Act if all reasonable measures to assure confidentiality are taken.

(d) The director of each state code department delivering health or social services shall prepare written notices describing the requirements under any federally funded programs for the disclosure of confidential information and the purposes for such access; and he shall promulgate regulations establishing procedures whereby each person being provided care or other services for which reimbursement will be sought through a federally funded program involving such disclosure will be given such notice at the outset of the delivery of services. Such notices shall provide advice regarding the individual's option not to receive treatment on a basis whereunder such disclosures are required.

Commentary on Model Law on Confidentiality of Health and Social Service Records

BY SANDRA NYE, J.D., M.S.W.

THIS MODEL ACT addresses and incorporates three allied legal concepts: confidentiality, privacy, and testimonial privilege. These are highly technical and frequently misunderstood. Privilege is an evidentiary concept which provides an exception to the general principle of law that courts have the right to every man's evidence. The concept has relevance only in context of the testimonial arena. A testimonial privilege (or shield law) permits those protected by it to withhold testimony or records, notwithstanding a subpoena (1). The right to privacy protects the individual from unsolicited, unwarranted intrusion in the conduct and affairs of his life—including the right to keep to himself information about himself (2). The right of a patient/client to confidentiality—and the concomitant duty of the care provider to maintain the patient/client's confidentiality—inheres in the contractual nature of the provider-patient/client relationship. Implied in the contract is a covenant not to disclose (3, 4).

Part of the complexity of this Model Act arises by reason of the legal principles on which it is based and which it intends to alter. In overturning existing law, every detail to be changed must be explicated. Any concept not expressly altered will remain the law. Thus, the Model Act must not only create and articulate novel concepts and procedures but must expressly eliminate or alter existing ones. For example, it is clearly established by case interpretation of statutory or common law privileges that the identity of a patient/client, the fact of the professional relationship, and purely clerical data—such as dates of service delivery—are not privileged communications and are, therefore, not protected from compelled disclosure in a legal proceeding (5). Further, the presence of a third person who is not a party to the provider-patient/client relationship (e.g., a family member or group member) "pollutes" any privilege that might have existed between the provider and the patient/client (6). Such technicalities as these have severely curtailed the efficacy of the communications privilege as a protection to psychiatric patients.

The Model Act is intended to serve as a basis for examining and proposing changes in local legislation. Although it represents the product of a thorough study of this subject and the combined thinking and expertise of many learned professionals, there are doubtless aspects that may be improved. The caveat to be kept in mind in working with the Act is that much of its phraseology consists of "terms of art." A knowledgeable lawyer should be consulted in any redrafting effort. In the limited space available for annotation, it is not possible to provide thorough explication and legal authority. We ask that the reader take on faith, for the time being, that what appear to be redundancy, prolixity, or tortured sentence construction translates in "legalese" as meaningful.

1. *Scope.* This Act defines both a communications privilege and a general law of confidential information. Thus, in addition to protecting confidential information from compelled disclosure in a judicial, legislative, or administrative proceeding, it also establishes a positive statutory duty on health and social service providers to maintain patient/client confidentiality. A salient principle of the Act is that all patient/client information given for the purpose of health care and social service delivery must be protected—irrespective of the nature of service delivered or the discipline or professional status of the care provider. This is a significant departure from most existing law, which makes irrational distinctions in protecting information as to care setting and care provider credentials. The needs of the patient/client for privacy and confidentiality do not differ according to whether the care provider is a social worker, a paraprofessional, or a psychiatrist. It should be public policy to mitigate fear of stigmatization (said to be the greatest barrier to seeking mental health services) so as to encourage individuals to seek necessary health and mental health care and social services.

2. *Definitions.* Explicit and detailed definitions are required to extend protection to categories of persons and data heretofore excluded by common law principles and certain statutes.

3. *Authorized Disclosures.* The nature of consent for disclosure is defined and delimited. This section clears up many existing ambiguities and procedural questions and outlines in detail the rights and duties of persons seeking disclosure, of care providers, and of patient/clients.

The minimum age at which consent may be given is established as 12 years. This is consistent with current child development theory recognizing the privacy and confidentiality needs of adolescents receiving mental health treatment and with existing federal and state legislation authorizing persons of this age to consent to certain types of treatment and other services. It is to be noted that parental notification will be automatic in most cases simply by reason of the parent's initiation of or involvement in the service delivered to the minor, or the minor's consent that disclosure be made to his/her parents. In the few cases in which the minor obtains services by reason of legal capacity to do so and does not authorize disclosure to his/her parents, the service provider who deems it necessary to notify the parents in order to protect the minor from serious injury or health hazard has the option under section 4 (c) to do so without the minor's consent or over his/her objection.

4. *Disclosures Without Authorization.* Although the underlying philosophy of the Act is that an individual has the right to control his/her private and confidential information, there is no question but that certain disclosures of such information are not only necessary but appropriate. In recognizing the "need to know," the following principles are essential:

a. Unauthorized disclosures should be kept to a mini-

mum, consistent with the needs of the patient/client and the exigencies of service delivery.

b. The primary duty of the service provider is to the patient/client. There is no *duty* upon a provider to protect third parties, but there may be instances in which the provider deems it in the patient/client's interest to disclose confidential information to protect the patient/client or another from serious harm. This is left to the *sole discretion* of the service provider, who is immunized against liability for any such disclosure in good faith.

The Patient/Client-Litigant Exception (subsection 4 (e)) is an almost universal exception to existing privilege laws. The adage that "confidentiality is to be a shield, not a sword" decrees that a patient/client waives any privilege he may have as to material relevant to the trial of a lawsuit in which he is a party. This section is based in part on guidelines set forth by Judge Shirley Hufstedtler in her brilliant dissenting opinion in *Caesar v. Mountanos* (7). It further excludes from the rubric of "mental condition" an action for pain and suffering per se and incorporates a refinement of Illinois law eliminating the exception in divorce cases (8). Strictures are placed on disclosure after the death of the patient/client because the threat of disclosure after death may serve to inhibit communications, particularly in mental health care delivery. This subsection clears up a problem presently existing in some jurisdictions that holds that the privilege expires with its holder.

Court-ordered examination (subsection 4 (f)). Service providers are frequently called upon to conduct examinations for trial purposes. Although clinical skills are utilized in such examinations, the information conveyed is intended to be disclosed, and communications made in the course of such examinations are not protected by a privilege. The relationship of examiner to the subject of the examination is not that of service provider and patient/client. Disclosure should, however, be limited in accordance with the purpose for which it is made.

5. *Waiver.* At common law, a communication not expressly asserted by its holder is deemed waived. This section clarifies the question of waiver and obviates certain "accidental" or "resulting" waivers.

6. *Ruling on Claims of Confidentiality.* This section protects, to the extent possible, confidential information during a controversy as to its discoverability or admissibility in a judicial or administrative proceeding. The person seeking disclosure has the burden of establishing discoverability or admissibility. The court is empowered to protect confidential information in appropriate cases in which there is no person in existence who is otherwise empowered to do so.

7. *Prescriptions.* The patient/client's need for confidentiality is balanced by the interest of the community in regulating drugs.

8. *Research.* Although confidential information disclosed by a patient/client in the course of receiving health and social services is intended by the patient/client to be utilized for his direct benefit in service provision, the value to the community in accessibility of data for research and development cannot be overlooked. This section provides access to data under strictures that will protect the patient/client.

9. *Mandatory Cautions.* The disseminator of confidential information is charged with the instruction of employees and disclosees as to the protection of the information he/she is disclosing.

10. *Remedies.* Civil (equitable and legal) relief is authorized for any person aggrieved by violation of this Act. In some jurisdictions violations of confidentiality statutes have been discouraged by criminal sanctions as well. Alternatives are provided herein.

11. *Employee Discipline.* This section is intended to enable employers to take appropriate action against employees who willfully or by gross negligence violate the Act. Employers are said to fear that, without such provisions, civil service and union procedures will effectively preclude disciplinary action against erring employees who are employed under civil service regulations or union contracts and whose wrongful acts not only injure patient/clients but also expose the employers to liability.

12. *Patient/Client Access to Information.* As a general principle, it is held that every person should have access to any record of information about him. If information is to be disclosed pursuant to consent, such access is probably mandatory. (Consent is not valid unless informed; one cannot give informed consent to disclose unless he/she has knowledge as to the content of the disclosure.) Further, a patient/client should have an opportunity and right to seek correction or at least enter his/her opinion into a record that contains an error or with which he/she disagrees. Experience with allowing patient/client access to records has been positive. At the same time, some clinicians are concerned that there may be occasional instances in which the patient/client will be harmed by such access or the treatment process compromised. A procedure is established that, although possibly cumbersome, will allow access as a general rule and will offer protection in cases in which the service provider deems access to be against the interest of the patient/client.

13. See annotation to Section 3, supra.

14. *Personal Notes.* This concept has been discussed for a number of years as a device by which clinicians can protect records of certain types of data (9). As the public insistence on patient/client right of access to records has grown, some care providers have been concerned about the effect on the individual who discovers unknown facts about him/herself or others or is exposed to speculations and interpretations of the clinician. Some information—although clinically relevant—may be so "sensitive" as to warrant exlcuding it from the case record entirely. Notes kept by the care provider for use in research, teaching, or supervision may contain material that is inappropriate for the clinical record. Further, by reason of the nature of mental health treatment, certain record content may be highly prejudicial to the patient/client if disclosure is compelled in a judicial or other proceeding.

The "personal notes" concept borrows from a protection afforded "the work product of the attorney." Certain specific types of material can be recorded in the clinician's "personal notes," which are to be utilized by the clinician for his/her own purposes and may not be disclosed or discovered. Concern has been expressed by some administrators and attorneys that this device will afford lazy, careless, or unscrupulous care providers a means of "hiding their wrongdoings" or, at best, neglecting their recordkeeping. Although it is not possible to preclude wrongdoing on the part of any person who is so inclined, the language of the section is eminently plain and clear as to the limited usage of "personal notes." The value of the device in protecting patients and enhancing service provision is deemed to outweigh any possible misuse potential.

15. *Group Health and Life Insurance.* Although the insurance industry denies the charge, there is a widespread belief that it is the major perpetrator of privacy and confidentiality offenses. In any case, care providers and patient/clients have expressed outrage over insurance company demands for in-

formation. A particular source of concern has been the practice of claims processing through employers. This section establishes parameters for data collection by insurors and requires that information about these parameters be supplied to the insured.

16. *Health and Life Insurance Disclosure of Information.* Of the several insurance company practices objected to by providers and patient/clients, one of the most decried is the exchange and dissemination of data among insurors. The practice is widespread; the insurors insist they have a need and right to protect themselves. The many documented abuses of this practice lead to the conclusion that it must be curbed. The interests of the individual and the community in encouraging health care—and particularly mental health care—are held to outweigh the financial interest of the insurors.

17. *State, County and Local Information Systems.* Electronic data collection and storage is perceived as a threat to individual liberty (10). Despite the best intentioned efforts at safeguarding data banks, they are vulnerable to invasion and misuse. Rules for protecting patient/client privacy and confidentiality are established in the light of the realities of audit and accountability requirements.

18. *Disclosures Required in Federally Funded Programs.* The practical exigencies of federal funding are recognized in this section, with safeguards established for confidential information being disclosed. Notice to the patient/client relative to disclosures and options is required.

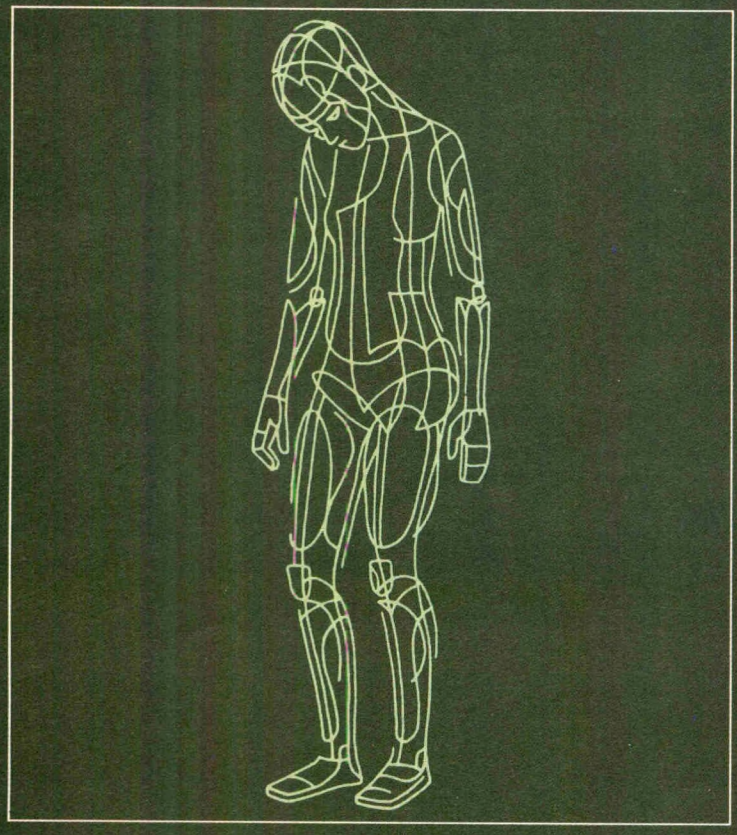
Foundations' Fund Fellowships for Sabbatical Research in Psychiatry and Its Basic Sciences

The Foundations' Fund for Research in Psychiatry announces a limited program of support for scholars on sabbatical leave in order to further their research and contribute to the knowledge of psychiatric diagnosis, treatment, and prevention. The sabbatical must be spent away from the home institution at an internationally recognized institution.

Applications are open to distinguished and creative investigators with demonstrated research contributions in the field who hold full-time positions in professional schools and graduate departments of universities or equivalent institutes of research. Applicants must be U.S. or Canadian citizens or permanent residents of the U.S. or Canada.

The deadline for receipt of applications is May 1 of the year preceding the proposed sabbatical.



Information may be obtained from:

Foundations' Fund for Research in Psychiatry

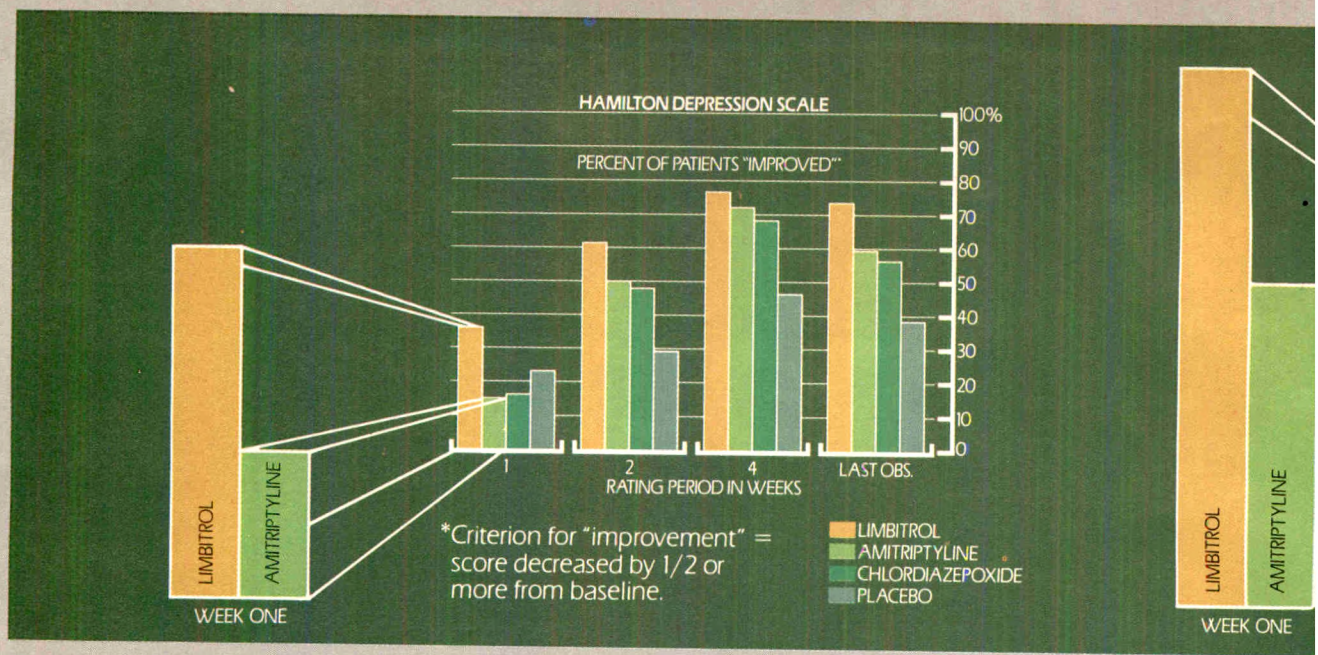
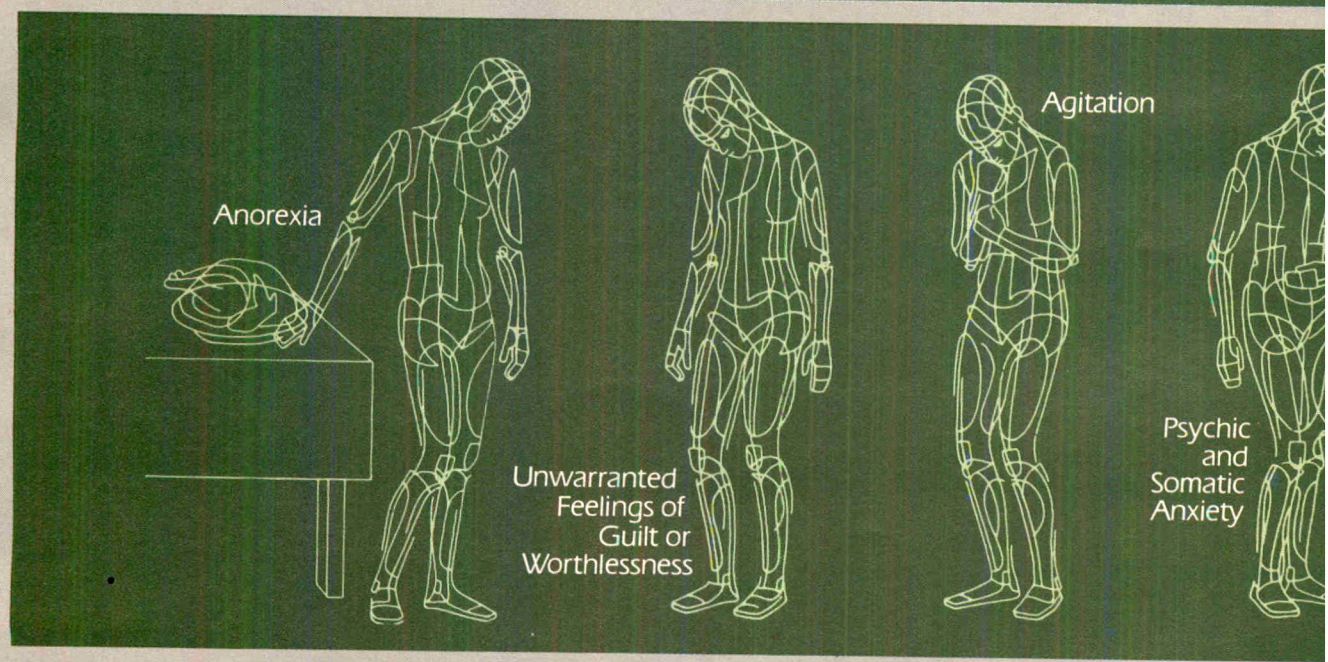
Limbitrol®

Provides the well established antidepressant effect of amitriptyline with the proven antianxiety effect of Librium® (chlordiazepoxide HCl)





For rapid relief of symptoms in moderate to severe depression and anxiety

In a rigidly controlled nationwide multicenter study, when compared to amitriptyline alone, Limbitrol achieved these superior results...

ROCHE

How to Initiate and Maintain Therapy

Select dosage strength appropriate for each patient

- Limbitrol 10-25 is recommended for most patients
- Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

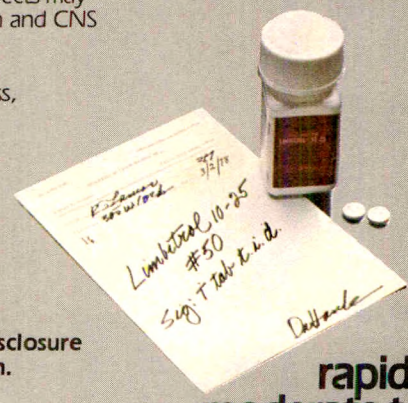
Specify daily dosage based on symptom severity

- An initial dosage of three tablets is recommended
- Dosage may be increased to six tablets or decreased to two tablets daily as necessary
- Once a satisfactory response is obtained, evaluate response, and if necessary, reduce dosage to smallest amount needed to maintain remission

Utilize dosage options to best accommodate individual patient needs

- T.I.D. or Q.I.D., familiar regimens best suited for patients who tolerate medication without undue drowsiness
- Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
- Entire dosage h.s. to take maximum advantage of the sedative effect

How to make each patient an informed patient



1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

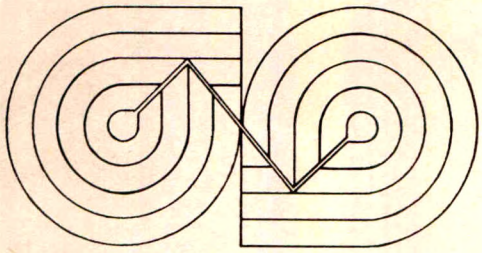
Limbitrol should not be used under t following circumstances

1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Should not be given with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for minimum of 14 days before cautiously ini ing Limbitrol therapy.
3. During the acute recovery phase follo ing myocardial infarction.

Limbitro

F
rapid relief
moderate to seve
depression and anxie

LIMBITROL® TABLETS
Tranquilizer–Antidepressant



Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).
Periodic liver function tests and blood counts are recommended during prolonged treatment.
Amitriptyline component may block action of guanethidine or similar antihypertensives.
Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive.
Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline.
Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs.
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergics: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urin tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomasti the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaund alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatme symptomatic and supportive. I.V. administration to 3 mg physostigmine salicylate has been repo to reverse the symptoms of amitriptyline poisonir See complete product information for manifestat and treatment.
Dosage: Individualize according to symptom se and patient response. Reduce to smallest effecti dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bed Single h.s. dose may suffice for some patients. L dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tab daily in divided doses, increased up to six tablet decreased to two tablets daily as required. Limb 5-12.5, initial dosage of three to four tablets daily divided doses, for patients who do not tolerate h doses.
Supplied: Limbitrol 10-25 tablets each containin mg chlordiazepoxide and 25 mg amitriptyline (a hydrochloride salt) and Limbitrol 5-12.5 tablets e containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles 100 and 500, Tel-E-Dose® packages of 100; Prescription Paks of 50.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

Must the MBD child take a controlled drug in school?

Not if he's taking Cylert® (pemoline) CIV 18.75, 37.5, 75 mg tablets

Children can be cruel. Their teasing about taking noontime medication can cause serious problems for the child with MBD.

Here's how Cylert eliminates this problem:

- Once a day dosage at home
- Eliminates mid-day school dose

In addition, Cylert offers these benefits:

- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies* .

*Copy of the Cylert Monograph available to Physicians on written request.

When not to use medication

Cylert should not be used for (and will not be effective in) simple cases of overactivity in school-age children.

Neither should it be used in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

A5

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans. Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) for use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laboratory animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on the fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannibalization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conception.

Adverse Reactions: Insomnia is the most frequently reported side effect of Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (white) in bottles of 100 (**NDC** 0074-6025-13)
37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)
75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored)
in bottles of 100 (**NDC** 0074-6088-13)

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

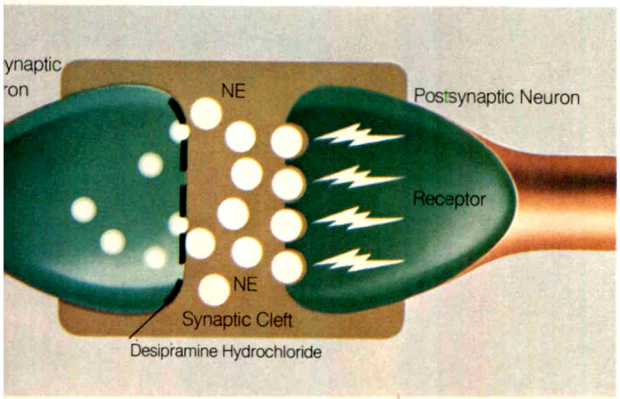
When your patient is clinically depressed...
"...everything I saw was negative."



...consider this potent blocker of norepinephrine re-uptake

The biogenic amine hypothesis states that depression may be associated with a deficiency of specific neurotransmitters–norepinephrine or serotonin—at brain receptor sites.[1] Tricyclics appear to block the re-uptake of specific neurotransmitters. Some tricyclics specifically block the re-uptake of serotonin; others block the re-uptake of norepinephrine.[2] Therefore, if your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic which blocks the re-uptake of a different neurotransmitter.

(Electron micrograph of human synaptic cleft.)

Norpramin®
lesipramine
ydrochloride
ablets NF)
,50,75,100,150 mg.

tent blocker
norepinephrine re-uptake
cording to current theory[1,3] some
yclic antidepressants may fail in certain
es of depression because they are not
iciently potent blockers of norepi-
hrine re-uptake. Laboratory studies
e shown that desipramine is the most
ent inhibitor of norepinephrine
uptake.[4] Norpramin may work in some
ents when other tricyclic antidepres-
ts do not.

onsider it now,
onsider it next.

Less anticholinergic activity
(See Warnings section.)
Studies in animals[5] and in normal human subjects[6,7] have shown that desipramine has significantly less anticholinergic activity than amitriptyline or doxepin. The single bond side chain is associated with lower anticholinergic activity than these other leading antidepressants. This may mean:

- less dry mouth
- less blurred vision
- less urinary retention

Helps patients remain calm but active
Norpramin does not usually inhibit normal activity although patients should be cautioned as to driving or operating machinery if drowsiness occurs.

In addition…

Begins to improve sleep patterns within one week in some patients[8]

- Norpramin helps relieve the sleep disturbances that often accompany depression.
- As the depression is relieved, the difficulty in falling asleep, restlessness, and early morning awakening diminish.

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. 2. This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. 3. USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. 4. USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. 5. The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. 6. In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. 2. If serious adverse effects occur, dosage should be reduced or treatment should be altered. 3. Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. 4. The drug may cause exacerbation of psychosis in schizophrenic patients. 5. Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. 6. Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. 7. Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. 8. The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. 9. This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. 10. Both elevation and lowering of blood sugar levels have been reported. 11. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

ADVERSE REACTIONS: Note: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enla ment and galactorrhea in the female; increase decreased libido, impotence, testicular swelling; el tion or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered function; weight gain or loss; perspiration, flus urinary frequency, nocturia; parotid swelling; dro ness, dizziness, weakness and fatigue, headache; pecia.

Withdrawal Symptoms: Though not indicative of ad tion, abrupt cessation of treatment after prolo therapy may produce nausea, headache, and mal

DOSAGE AND ADMINISTRATION: Not recommended fo in children. Lower dosages are recommended for el patients and adolescents. Lower dosages are recommended for outpatients compared to hospita patients, who are closely supervised. Dosage shou initiated at a low level and increased accordin clinical response and any evidence of intolera Following remission, maintenance medication ma required for a period of time and should be at the lo dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 20 per day. In more severely ill patients, dosage ma further increased gradually to 300 mg./day if neces Dosages above 300 mg./day are not recommende

Dosage should be initiated at a lower level increased according to tolerance and clinical respe

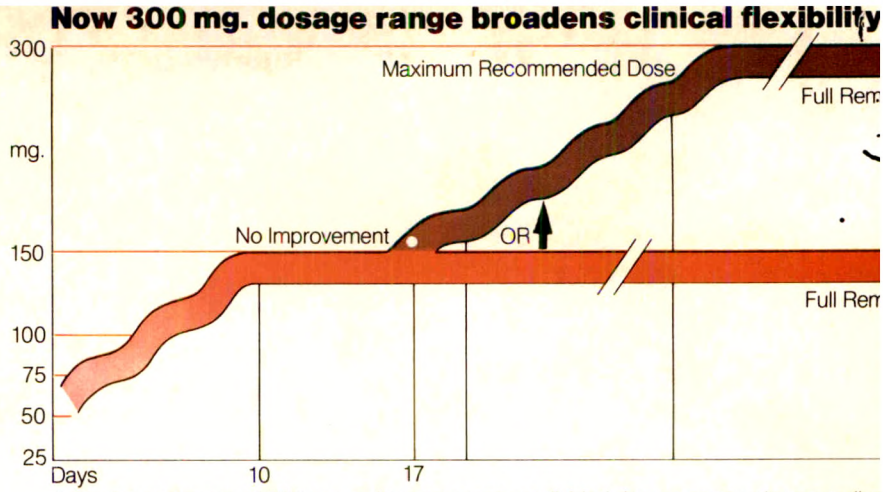
Treatment of patients requiring as much as 30 should generally be initiated in hospitals, where re visits by the physician, skilled nursing care, and quent electrocardiograms (ECG's) are available.

The best available evidence of impending to from very high doses of Norpramin is prolongation QRS or QT intervals on the ECG. Prolongation of th interval is also significant, but less closely corre with plasma levels. Clinical symptoms of intolera especially drowsiness, dizziness, and postural hyp sion, should also alert the physician to the nee reduction in dosage. Plasma desipramine measure would constitute the optimal guide to dosage mo ing.

Initial therapy may be administered in divided d or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescen geriatric dose is 25 to 100 mg. daily.



Dosage should be initiated at a lower level increased according to tolerance and clinical resp to a usual maximum of 100 mg. daily. In more severe patients, dosage may be further increased to 150 day. Doses above 150 mg./day are not recommend these age groups.

Initial therapy may be administered in divided d or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a di sion of symptoms and treatment of overdose.

Product Information as of April, 1978

A maximum dosage of 300 mg. a day, as a single or divided dose, may now be prescribe Norpramin. Since inadequate dosage is thought to be one of the major causes of treatme failure, the new therapeutic range should prove clinically helpful. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

CALM
AND
ALERT*
THE
PATIENT ON
VERSTRAN
(prazepam)

Smooth, consistent anxiolytic action is the reason.

Proven efficacy

- Effective symptomatic relief of anxiety, whether psychic or somatic in origin
- Therapeutic response achieved with first dose
- Verstran—a suitable antianxiety alternative to diazepam

Established safety

- Virtually no drowsiness* in most Verstran patients (less than 10%)
- Other side effects, if present, are minimal†
- Verstran is appropriate concomitant therapy in most somatic disorders‡
- No accumulation after steady state is reached

Dosage versatility

- The simplicity of a single-strength 10-mg scored tablet, for easy titration and improved patient compliance
- The flexibility of *once daily*§ dosage
- The option of a *b.i.d.* dosage regimen, gradually adjustable within a range of 20 to 60 mg/day

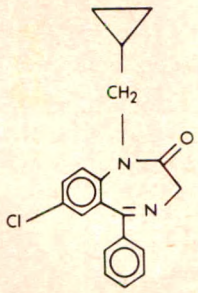
As with all CNS-acting agents, patients should be cautioned against driving, drinking, or engaging in hazardous activities.

Data on file, Warner/Chilcott Medical Department.

See package insert.

At bedtime.

Before prescribing, see complete product information on the following page.



TO ENHANCE PATIENT RESPONSIVENESS CONSIDER

VERSTRAN (prazepam) Ⓒ IV

VERSTRAN® (prazepam) Ⓒ IV

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam), a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows:

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (±15 s.d.) hours before and 70 (±10 s.d.) hours after multiple dosing — a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

The effectiveness of Verstran (prazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warnings: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:

Use in Pregnancy and Lactation:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use: Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (5.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, transient skin rashes, swelling of feet, joint pains, various genitourinary complaints, blurred vision, and syncope. Single nightly dose, controlled trials of variable dosages showed a dose-related incidence of these same side effects. Transient and reversible aberrations of liver function tests have been reported, as have slight decreases in blood pressure and increases in body weight.

These findings are characteristic of benzodiazepine drugs.

Overdosage: As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

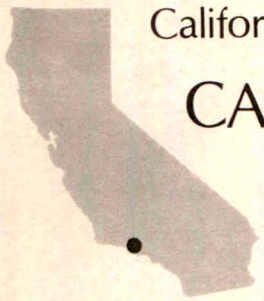
If vomiting has not occurred spontaneously, it should be induced. Immediate gastric lavage is also recommended. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension though unlikely, may be controlled with Levophed® (levarterenol bitartrate) or Aramine® (metaraminol bitartrate). Caffeine and Sodium Benzoate Injection USP, may be used to counteract central nervous system depressant effects.

Dosage and Administration: Verstran (prazepam) is administered orally in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 20 to 60 mg daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a divided daily dose of 10 mg to 15 mg. (See Precautions.)

Prazepam may also be administered as a single dose daily at bedtime. The recommended starting nightly dose is 20 mg. The response of the patient to several days' treatment will permit the physician to adjust the dose upward or, occasionally, downward to maximize antianxiety effect with a minimum of daytime drowsiness. The optimum dosage will usually range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.



How Supplied: Verstran (prazepam) 10 mg light blue scored tablets in bottles of 100 (N 0047-0276-51) and 1000 (N 0047-0276-60).

STORE BETWEEN 59°–86° F (15°–30° C).

offers

FELLOWSHIPS

in

POST-DOCTORAL RESEARCH TRAINING

Fellowship positions are available through N.I.M.H.-supported programs that provide basic preparation for research in areas relevant to mental health, the brain and behavior. The program is available to persons who have completed three years of residency training in psychiatry or the requirements for the Ph.D. in a behavioral or social science.

Emphasis is on acquiring proficiency in the fundamental principles of research strategy, methodology and techniques currently employed in laboratory and clinical studies in psychiatry. The traineeships stress active participation in research work under the supervision of faculty preceptors, supplemented by a curriculum of seminars and workshops.

Appointments are full-time and are for one to two years.

The patient with clinically significant depressio

He's getting better...

and ELAVI

(AMITRIPTYLINE HCl | MSD

is helping

Helping with symptom relief

ELAVIL usually relieves a broad range of symptoms associated with depression, including sleep disturbance, one of the most frequently observed in the "constellation of symptoms," and usually the first symptom to respond to therapy.

And, the anxiety-reducing sedative component extends the drug's clinical value when depression is accompanied by symptoms of anxiety. The drug may impair mental or physical abilities required in the performance of hazardous tasks and may enhance the response to alcohol.

Helping with convenient dosage regimens

ELAVIL offers a variety of convenient dosage regimens. A once-daily bedtime regimen may be an effective prescribing option, particularly when taken by a depressed patient experiencing sleep disturbance. ELAVIL can also be prescribed in divided daily doses. Prescriptions should be written for the smallest amount feasible.

Providing a wide range of tablet strengths

ELAVIL offers six color-coded tablets, available in the following strengths: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg. And for special circumstances, an injectable form is available. Injection ELAVIL is supplied in 10-ml vials, 10 mg/ml.

TABLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
INJECTION: 10 mg per ml

Elavil®

(AMITRIPTYLINE HCl | MSD)

helping relieve the symptoms of clinically significant depression

MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

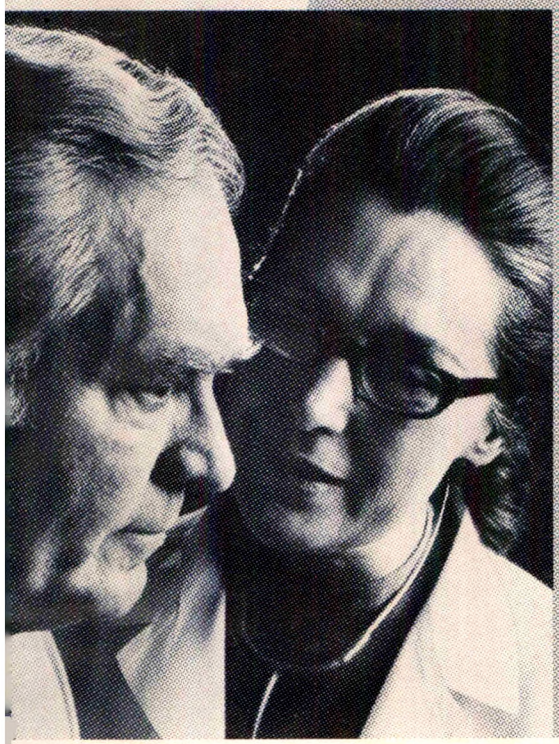
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative-or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., Inc., West Point, Pa. 19486



J8EL26(116)

proven antianxiety

Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® ℞
chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- ☐ An unsurpassed safety record
- ☐ Minimal effect on mental acuity, in proper dosage
- ☐ Predictable patient response
- ☐ Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Please see next page for summary of product information.

Librium® 5mg, 10mg, 25mg capsules
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral–Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d.* *Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

PSYCHIATRIST

Chief, Psychiatry Service sought by large University-affiliated teaching hospital. Applicant must be board certified in psychiatry and qualified to hold professorial academic rank. Experience in adminstration of a large psychiatric service essential. Organizational ability and academic background necessary. Equal Employment Opportunity and Affirmative Action Employer. Salary up to $47,500 plus special pay bonus and excellent fringe benefits. Applicants may apply to Chief of Staff, VA Medical Center, North Chicago, Illinois 60064, or call (312) 689-1900, extension 2841.

Internationally based rehabilitation and health planning agency in New York City seeks upwardly mobile, flexible and creative Board eligible (or certified) **psychiatrist** for high level administrative position. Candidates must be able to travel. Duties include supervision of 500 in-resident patients in 5 states, program design, and the articulation of health care issues for purposes of social change. Salary is $50,000 plus (negotiable). We are interested in hiring for this position as quickly as possible. Please send resume to Ms. Maggie Pike, Odyssey Institute, 24 West 12th Street, N.Y., N.Y. 10011.

ADRIFT IN A SEA OF CONFUSING VOICES

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema; urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

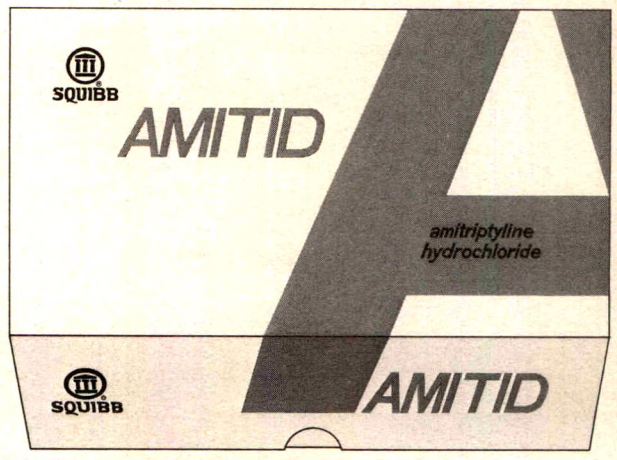
TRIFLUOPERAZINE HCl

A First Choice for Therapy

You know what to expect from antidepressant therapy;

...but does your patient?



You know that it generally takes two or three weeks for tricyclic therapy to begin working in depression... and that some side effects may be encountered. But, in all likelihood, your patient doesn't.

To lessen the time you spend in explanation and to increase patient compliance, we've included a supply of patient information booklets as part of the special starter kit designed to introduce you to Amitid. Entitled "COMING BACK FROM DEPRESSION," the booklet offers encouragement to depressed patients, helps you explain the basic facts about depression and outlines some of the things to be expected during therapy. The kit also contains generous starter supplies of the 25 mg tablets of Amitid, along with descriptive literature.

Amitid offers all the known clinical advantages of amitriptyline, with documented bioequivalence to the leading brand. Yet Amitid is priced so your patients can realize significant cost savings on prescriptions over the major branded amitriptylines.* Added to your counseling and the new patient booklet, these savings should help ease the burden of depression... just a little bit more!

Based on manufacturers' published prices as of August 1, 1978.

To receive your starter kit, just fill in and mail the coupon below.

Mail to:
E. R. Squibb & Sons, Inc.

Introducing
Amitid™
Amitriptyline Hydrochloride Tablets USP

lowers the cost, not the quality, of antidepressant therapy

Please see following page for brief summary.

SQUIBB®

Amitid™ (Amitriptyline Hydrochloride Tablets USP)

DESCRIPTION: Amitriptyline hydrochloride is a dibenzocycloheptadiene derivative available for oral administration as FILMLOK® tablets (FILMLOK is a Squibb trademark for veneer-coated tablets).

INDICATIONS: For relief of symptoms of depression alone or accompanied by anxiety. Endogenous depression is more likely to be alleviated than are other depressive states.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to amitriptyline. Do not administer concomitantly with a monamine oxidase (MAO) inhibitor since hyperpyretic crises, severe convulsions, and deaths occurred when tricyclic antidepressants and MAO inhibitors were administered simultaneously. When an MAO inhibitor is to be replaced by amitriptyline, allow 14 days to elapse after discontinuation of the former and then initiate amitriptyline cautiously and gradually increase dosage until optimum response is achieved. Amitriptyline is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS: Amitriptyline may block antihypertensive action of guanethidine or similarly acting drugs. Use with caution in patients with history of seizures and (because of atropine-like action of amitriptyline) in patients with history of narrow-angle glaucoma (even average doses may precipitate an attack), increased intraocular pressure, or urinary retention. Closely watch patients with cardiovascular disorders since, in addition to having caused myocardial infarction and stroke, tricyclic antidepressants (including amitriptyline) particularly with high dosage have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Close supervision is required when amitriptyline is given to hyperthyroid patients or those on thyroid medication. Amitriptyline may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving a motor vehicle. Bear in mind that in patients who may use alcohol excessively the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Usage in Pregnancy: Safe use during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women who may become pregnant, weigh the possible benefits against the possible hazards to the mother and child. Animal reproduction studies have been inconclusive, and clinical experience has been limited.

Usage in Children: At the present time, not recommended for patients under 12 years of age because of lack of experience with use in children.

PRECAUTIONS: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances the dose of amitriptyline may be reduced or a major tranquilizer may be administered concurrently.

Closely supervise and carefully adjust dosage in concomitant use with anticholinergic or sympathomimetic drugs, including combination of epinephrine and local anesthetics. Paralytic ileus may occur with concomitant use of tricyclic antidepressants and anticholinergic-type drugs. Caution is advised if used concurrently with large doses of ethchlorvynol since transient delirium has been reported when one gram of that drug and 75 to 150 mg of amitriptyline HCl were administered. Amitriptyline may enhance response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs. Potentially suicidal patients should not have easy access to large quantities of the drug. Prescriptions should be written for the smallest amount feasible. Limit concurrent administration of this drug and electroshock therapy to patients for whom it is essential since the hazards associated with such therapy may be increased. Discontinue this drug, when possible, several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use amitriptyline with caution in presence of impaired liver function.

ADVERSE REACTIONS: NOTE: A few of the adverse reactions listed below have not been reported with this specific drug, but each of the reactions should be considered when administering amitriptyline because of pharmacological similarities among tricyclic antidepressants.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, and stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness; tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; and syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, and dilatation of the urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, and edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, and thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, and black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, and elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, and alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available for oral administration in tablets providing 10, 25, 50, 75, and 100 mg amitriptyline hydrochloride. The 10, 25, and 50 mg tablets are available in bottles of 100 and 1000. The 75 and 100 mg tablets are available in bottles of 100.

Tranxene® CV

(CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS
Brief Summary

ABBOTT

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, followed by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in divided doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 mg. in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 (NDC 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

8088271

Awake on the job, yet anxiety controlled

Troublesome drowsiness uncommon. Tranxene lets you manage anxiety in most patients without problem sedation. Any initial drowsiness is usually transient. By avoiding excessive sedation, Tranxene helps you calm patients without compromising their capacities.*

'STELAZINE' HELPS FIND THE WAY BACK

The schizophrenic patient is often surrounded by confusing voices, bewildering thoughts, fright and anxiety. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, convenient b.i.d. 'Stelazine' usually does not cause excessive sedation, which means that 'Stelazine' works with and not against your therapeutic program.

After 18 years of extensive research and clinical experience, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer side effects than 'Stelazine'. These facts make 'Stelazine' a first choice for therapy.

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Additive effect is possible with other C.N.S. depressants. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions; peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./mL.; and Concentrate (intended for institutional use only), 10 mg./ml.

Announcing a Special Issue of **The American Journal of Psychiatry** c

DEPRESSION and ALCOHOLISM

This mid-April special issue, included in regular subscriptions to the *American Journal of Psychiatry,* focuses on two topics of intense concern to the psychiatric profession: depression and alcoholism.

Containing 30 original articles, it covers the spectrum of diagnostic considerations, treatment, management and complications, etiology and phenomenology. The emphasis throughout is clinical. While several articles explore new work on alcoholism and on the relationship between depression and alcoholism, current studies on depression dominate this valuable collection.

Partial List of Contributors

David Avery, M.D., Karen Beckman, Robert H. Belmaker, M.D., Walter A. Brown, M.D., Jesse O. Cavenar, Jr., M.D., Alberto DiMascio, Ph.D.,* David L. Dunner, M.D., Larry Ereshefsky, Pharm.D., Ronald R. Fieve, M.D., Eric W. Fine, M.D., Evelyn L. Goldberg, Sc.D., John E. Hamm, M.D., John E. Helzer, M.D., Shirley Y. Hill, Ph.D., Martin H. Keeler, M.D., Gerald L. Klerman, M.D., James H. Kocsis, M.D., Eleftherios Lykouras, M.D., Anthony J Marsella, Ph.D., Roy J. Mathew, M.D., D.P.M., Demmie Mayfield, M.D., Jerome A. Motto M.D., Michael R. Weissman, Ph.D., Steven J. Wolin, M.D.

*deceased

Partial List of Topics

Diagnosis

Depression simulating organic brain disease — diagnosis and lithium treatment of manic-depressive disorder in the retarded — delineation of an MMPI symptom pattern unique to lithium responders

Treatment, Management

Depression treated with imipramine and ECT — possible cardiovascular effect of lithium — lithium maintenance: factors affecting outcome — efficacy of drugs and psychotherapy in the treatment of acu depressive episodes

Etiology, Phenomenology

Life events at the onset of bipolar affective illness childhood depression: interpersonal interactions a depressive phenomena — drug abuse among alc holic women — psychiatric problems in women d ing alcoholic detoxification — life events, coping, stress, and depressive symptomatology

A special Guest Editorial by Morris A. Lipton, Ph.D., M.D., provides a unifying perspective this special issue.

Extra copies of the April 1979 Special Issue (the 2nd April issue) will be available at $2.25 (domestic), $2.90 (foreign). *Payment must be included with order.* Order from:

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions; and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality, and authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications (no précis is used in the Clinical and Research Reports section). The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material; a complete review of the literature is rarely desirable. *Accuracy of citation is the author's responsibility.* References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do *not* arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below and on the next page, double-spaced *throughout* (not just a line between references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26

2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2–6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

- **Overview: Efficacy and Safety of the Rapid Neuroleptization Method with Injectable Haloperidol**

  By Patrick T. Donlon, John Hopkin, and Joe P. Tupin

VOICES
.accusatory, derogatory, ondemning, commanding.

Navane (thiothixene) rapidly controls auditory hallucinations as well as agitation and hostility patterns they frequently generate.

Rapid control of psychotic symptoms on admission

Navane provides effective, rapid control of the major symptoms of psychosis luding hallucinations, delusions, agitation, hostility, and thought disorders.[1-5] vane promotes rapid progress, usually without the over-sedation or cardio-cular problems that can impede the therapeutic course.

Continued long-term improvement

Because Navane provides long-term outpatient control of psychotic symptoms, an enable many patients to function effectively at home and on the job and to ıst rapidly to the community.[6]

Effectiveness rarely compromised by adverse reactions

Navane allows patients to remain alert and active, seldom causing over-ation or drowsiness.[7] Hypotension and other cardiovascular reactions[5,6,8] are lom reported and the occurrence of unpleasant anticholinergic side effects such lry mouth or constipation is rare.[9] If extrapyramidal symptoms occur, they are ıally readily controlled through dosage adjustments or antiparkinson agents.

Rapid control
Long-term improvement
Navane®
(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml. Intramuscular 2 mg./ml.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
(thiothixene hydrochloride) Concentrate: 5 mg/ml,
Intramuscular: 2 mg/ml

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*—Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration—As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage for Dosage recommendations for Navane Capsules and C centrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder cor tions, an initial dose of 2 mg three times daily. If indicate subsequent increase to 15 mg/day total daily dose is of effective.

In more severe conditions, an initial dose of 5 mg tv daily.

The usual optimal dose is 20 to 30 mg daily. If indicated increase to 60 mg/day total daily dose is often effect Exceeding a total daily dose of 60 mg rarely increases beneficial response.

Overdosage. Manifestations include muscular twitch drowsiness, and dizziness. Symptoms of gross overdosage include CNS depression, rigidity, weakness, torticollis, tren salivation, dysphagia, hypotension, disturbances of gait coma.

Treatment: Essentially symptomatic and supportive. Navane oral, early gastric lavage is helpful. For Navane oral Intramuscular, keep patient under careful observation maintain an open airway, since involvement of the ex pyramidal system may produce dysphagia and respirat difficulty in severe overdosage. If hypotension occurs, standard measures for managing circulatory shock should used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phen ephrine are the most suitable drugs. Other pressor age including epinephrine, are not recommended, sin phenothiazine derivatives may reverse the usual pressor act of these agents and cause further lowering of blood pressure

If CNS depression is present, recommended stimula include amphetamine, dextroamphetamine, or caffeine sodium benzoate. Picrotoxin or pentylenetetrazol should avoided. Extrapyramidal symptoms may be treated w antiparkinson drugs.

There are no data on the use of peritoneal or hemodialy but they are known to be of little value in phenothia intoxication.

How Supplied. Navane (thiothixene) is available as caps containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene bottles of 100 and 1,000. Navane is also available as caps containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate available in 120 ml (4 oz.) bottles with an accompany dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, 10 mg, and in 30 ml (1 oz.) bottles with an accompany dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml c tains thiothixene hydrochloride equivalent to 5 mg thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solu is available in a 2 ml amber glass vial in packages of 10. Each contains thiothixene hydrochloride equivalent to 2 mg thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, propyl gallate 0.02% w/v.

DEPRESSION IN CHILDREN AND ADOLESCENTS

An outstanding, long-awaited volume which critically examines the phenomenon of depression in children and adolescents from a wide range of historical, developmental and clinical perspectives. Recognized authorities from diverse mental health disciplines present the most current research concerning etiology and treatment of depression and assess the relationship between depression and family dynamics. Richly illustrated with case materials, this work offers valuable insight into the treatment of physically handicapped, abused and self-destructive children whose problems often result in profound depression. Also provided is an extensive annotated bibliography containing the most significant clinical and theoretical literature in this recently acknowledged area of child psychiatry.

This work will prove an invaluable reference source for all psychotherapists, psychiatrists and related mental health professionals involved in the understanding, prevention and treatment of depression in childhood and adolescence.

DeMartino, Manfred F., M.A., Editor

HUMAN AUTOEROTIC PRACTICES

Foreword by Dr. Albert Ellis

This comprehensive volume which reflects contemporary thinking, current research, and clinical findings of eminent sexologists, such as Alex Comfort, Havelock Ellis, Helen Kaplan, Masters and Johnson, and James L. McCary, as well as sex therapists, psychotherapists, and clinicians on the subject of autoeroticism, is a landmark work. Not only do the authors make it clear that the practice of autoeroticism is normal and healthy in females and males of any age and in many different circumstances, but some psychotherapists also state that the absence of masturbatory behavior during one's life may lead to sexual problems.

". . . the definitive work on the subject."

—Albert Ellis, Ph.D.

1979/Feb. 304 pp. (approx.) LC 78-8766

0-87705-403-7 Paper $7.95

Anderson, Robert, A., M.D.

STRESS POWER!

How to Turn Tension into Energy

Tension is becoming increasingly acknowledged as the greatest single factor in the production of physical and emotional disability, distress, disease and death. This seminal book provides a major breakthrough on the practical methods of understanding and confronting these destructive patterns, and utilizing tension and stress in a creative way through establishing and meeting positive self-directed goals. The author, with over twenty years experience in the medical profession, has extrapolated techniques from such diverse sources as transactional analysis, gestalt therapy, psychodrama and psychosynthesis. He here presents, with clarity and intelligence, a work with practical self-guided exercises for transforming the tensions, resulting from the everyday stress of modern life, into a positive source of energy.

"A very readable and informative book. I can highly recommend it as an introduction to the stress concept and ways to cope with a stressful life."

—Hans Selye, M.D., Ph.D.

1978/Oct. 225 pp. LC 78-8308
0-87705-328-6 $9.95

Rueveni, Uri, Ph.D.

NETWORKING FAMILIES IN CRISIS

This seminal work aims to familiarize the professional audience with the exciting new technique of mobilizing the extended system of family, relatives, friends and neighbors for helping a family during times of emotional crisis. The book effectively demonstrates that, in numerous instances, use of this extended network results in constructive change in situations which had previously seemed beyond the scope of professional guidance.

"Dr. Rueveni's book clearly shows the technique and theory he uses in extending the boundaries of professional intervention in families in severe crisis."

—Ross Speck and Joan Speck

Chiland, Colette, M.D., Ph.D., Editor

LONG-TERM TREATMENTS OF PSYCHOTIC STATES

The most comprehensive collection to date on the subject of long-term treatment of psychotic states, this distinctive reference tool with contributions from fifty-four distinguished experts in the field deals with the subject in terms of epidemiology, etiology, chronicity, and treatment from a multiplicity of viewpoints and against the background of diverse experiential milieus.

". . . this is an extremely rich book, one that should be quite valuable to clinicians working with psychotic patients in any number of settings."

—Smith College Studies in Social Work

". . . well worth owning as a basic reference to current thinking . . . I would hope that one effect of this collection would be to regenerate interest in this basic area among professionals."

—Leon Shapiro, M.D. Cornell Medical Center

". . . a substantive survey of what is taking place in this often hidden corner of our work."

—American Journal of Psychiatry

The patient with clinically significant depressio

He's getting better...

and ELAVI

(AMITRIPTYLINE HCl | MSI

.s helping

elping with ymptom relief

.AVIL usually relieves a broad range of symptoms sociated with depression, including sleep distur- nce, one of the most frequently observed in the onstellation of symptoms," and usually the first symp- n to respond to therapy.

d, the anxiety-reducing sedative component extends e drug's clinical value when depression is accom- nied by symptoms of anxiety. The drug may impair ental or physical abilities required in the performance hazardous tasks and may enhance the response alcohol.

elping with convenient osage regimens

.AVIL offers a variety of convenient dosage regimens. once-daily bedtime regimen may be an effective pre- ribing option, particularly when taken by a depressed tient experiencing sleep disturbance. ELAVIL can so be prescribed in divided daily doses. Prescriptions ould be written for the smallest amount feasible.

roviding a wide range f tablet strengths

.AVIL offers six color-coded tablets, available in the lowing strengths: 10 mg, 25 mg, 50 mg, 75 mg,) mg, and 150 mg. And for special circumstances, injectable form is available. Injection ELAVIL is pplied in 10-ml vials, 10 mg/ml.

BLETS: 10 mg, 25 mg, 50 mg, 75 mg, 100 mg, and 150 mg
JECTION: 10 mg per ml

Elavil®

AMITRIPTYLINE HCl | MSD)

elping relieve the ymptoms of clinically ignificant depression

MSD
MERCK SHARP & DOHME

Contraindications: Known hypersensitivity. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with amitriptyline HCl. Initiate dosage of amitriptyline HCl cautiously with gradual increase in dosage until optimum response is achieved. Not recommended during the acute recovery phase following myocardial infarction.

Warnings: May block the antihypertensive action of guanethidine or similarly acting compounds. Should be used with caution in patients with a history of seizures or a history of urinary retention, or with angle-closure glaucoma or increased intraocular pressure; in patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely; arrhythmias, sinus tachycardia and prolongation of the conduction time have been reported, particularly with high doses; myocardial infarction and stroke have been reported with drugs of this class. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Safe use during pregnancy and lactation has not been established; in pregnant patients, nursing mothers, or women who may become pregnant, weigh possible benefits against possible hazards to mother and child. Not recommended for patients under 12 years of age.

Precautions: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances, the dose of amitriptyline HCl may be reduced or a major tranquilizer, such as perphenazine, may be administered concurrently.

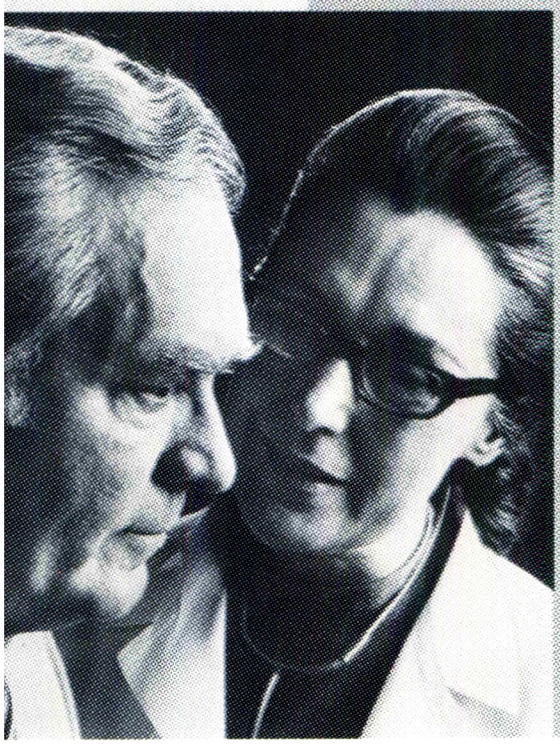
When given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required; paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs. Use cautiously in patients receiving large doses of ethchlorvynol, since transient delirium has been reported on concurrent administration. May enhance the response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains until significant remission occurs. Potentially suicidal patients should not have access to large quantities of this drug. Prescriptions should be written for the smallest amount feasible. Concurrent electroshock therapy may increase the hazards associated with such therapy; such treatment should be limited to patients for whom it is essential. When possible, discontinue the drug several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use with caution in patients with impaired liver function.

Adverse Reactions: *Note:* Included in this listing are a few adverse reactions not reported with this specific drug. However, pharmacological similarities among the tricyclic antidepressant drugs require that each reaction be considered when amitriptyline is administered. *Cardiovascular:* Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, dilatation of urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, black tongue, rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise; these are not indicative of addiction.

Overdosage: Hospitalize as soon as possible all patients suspected of having taken an overdose. Treatment is symptomatic and supportive. In addition, the intravenous administration of 1 to 3 mg physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage should be repeated as required, particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine.

How Supplied: Tablets containing 10 mg and 25 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100, 1000, and 5000; tablets containing 50 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100 and 1000; tablets containing 75 mg and 100 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 100; tablets containing 150 mg amitriptyline HCl, in single-unit packages of 100 and bottles of 30 and 100; for intramuscular use, in 10-ml vials containing per ml: 10 mg amitriptyline HCl, 44 mg dextrose, 1.5 mg methylparaben and 0.2 mg propylparaben as preservatives, and water for injection q.s. 1 ml.

For more detailed information, consult your MSD representative or see full prescribing information. Merck Sharp & Dohme, Division of Merck & Co., INC., West Point, Pa. 19486



J8EL26 (116)

proven antianxiety

Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® IV
chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- An unsurpassed safety record
- Minimal effect on mental acuity, in proper dosage
- Predictable patient response
- Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Please see next page for summary of product information.

Librium® 5mg, 10mg, 25mg capsules
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral—Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d. Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

A Psychiatric Glossary

Edited by a subcommittee of the AMERICAN PSYCHIATRIC ASSOCIATION Committee on Public Information.

The new Fourth Edition marks a striking expansion of definitions: 400 terms have been added and many of the terms appearing in earlier editions have received revised explanations. In addition to the GLOSSARY's continuing value to lawyers, teachers, journalists, social workers, and others, the new edition will be useful to medical students and first year residents in psychiatry.

Some major changes in the Fourth Edition:

- Expansion from 102 to 156 pages to accommodate 400 new terms
- New tables of terms in seven areas of contemporary concern
  - Drugs Used in Psychiatry
  - Legal Terms
  - Neurologic Deficits
  - Psychological Tests
  - Research Terms
  - Schools of Psychiatry
  - Sleep Disorders
- A comprehensive set of terms used in behavior therapy is included for the first time.

Paperback edition—$3.00 each, (See coupon for bulk discounts), may be ordered from the AMERICAN PSYCHIATRIC ASSOCIATION, Publications Sales, 1700 18th St. N.W., Washington, D.C. 20009.

Hardback edition—$7.95 may be ordered from Basic Books, Inc., 10 East 53rd Street, New York, New York 10022.

Treating the needs of the "whole" patient.

PSYCHOLOGICAL INTERVENTIONS IN MEDICAL PRACTICE

By **James J. Strain, M.D.**, Director, Liaison Service, Montefiore Hospital and Medical Center, and Associate Professor of Psychiatry, Albert Einstein College of Medicine

The chronically ill often react to their condition with rage and self destructiveness, making it difficult to secure vital cooperation in working out a treatment program. Dr. Strain, a leading liaison psychiatrist, equips the non-psychiatrist physician with the basic knowledge needed to help patients develop a disease-compatible lifestyle. Three demonstration projects are also included to provide practical details on implementing a psychologically-geared primary care program in a hospital or private practice.

1978 224 pages Illustrated $12.50

PSYCHOLOGICAL CARE OF THE MEDICALLY ILL: A PRIMER IN LIAISON PSYCHIATRY

By **James J. Strain, M.D.** and **Stanley Grossman, M.D.**, Associate Attending Psychiatrist, Montefiore Hospital and Medical Center, Bronx, New York

Focusing on patients' psychological reactions to illness and hospitalization, this guide covers a wide range of strategies for optimizing medical care, including specific techniques for evaluating and treating depression, hypochondriasis, and the problem of pain.

1975 223 pages Illustrated $12.50

PSYCHOPHARMACOLOGY IN THE PRACTICE OF MEDICINE

Edited by **Murray E. Jarvik, Ph.D., M.D.**, Professor of Psychiatry and Pharmacology, School of Medicine, University of California, Los Angeles

The vast amount of psychopharmacologic literature on the clinical use of psychotropic agents has been pulled together in this timely reference. Fully 36 authorities make contributions, covering such topics as the placebo phenomenon, drugs and sexual dysfunction, treating hyperactivity, drugs of dependence, treating opioid addiction, and psychotherapeutic drugs in childhood and adolescence. There's a handy format throughout, quickly pinpointing the indications, contraindications, side effects, mode of action, and pharmacology of a broad range of drugs.

1976 553 pages Illustrated $20.50

PRACTICAL PSYCHIATRY IN MEDICINE

By **John B. Imboden, M.D.**, Psychiatrist-in-Chief, Sinai Hospital of Baltimore, Ind.; Associate Professor, Johns Hopkins University and **John Chapman Urbaitis, M.D.**, Associate Chief of Psychiatry, Johns Hopkins University

Here is a comprehensive yet concise examination of the most frequent psychiatric problems a physician encounters in daily practice. As the authors state, "the question which confronts the practicing physician is not *whether* he incorporates psychiatry in his clinical work, but how deliberately and how *well* he does so." With this practical view, they go on to discuss diagnostic assessment and clinical management related to: suicidal behavior and other psychiatric emergencies, sexual dysfunction, alcoholism, drug dependence, organic brain syndromes, neuroses and personality disorders, conversion disorders and hypochondriasis, mood disorders, and schizophrenic disorders.

1978 320 pages Illustrated $9.50

IMAGE FORMATION AND COGNITION SECOND EDITION

By **Mardi J. Horowitz, M.D.**, Professor of Psychiatry, University of California, School of Medicine, San Francisco and faculty member of the San Francisco Psychoanalytic Institute

Abound with clinical and pictorial illustrations, this new second edition offers lucidity, careful scholarship, and avoidance of technical jargon in advancing several interrelated theories on the formation of images. Psychoanalytic, psychological, and neurobiological viewpoints are equally represented, resulting in a broad understanding of the emotional, self-stimulating, and problem-solving aspects of human thought and subjective experience.

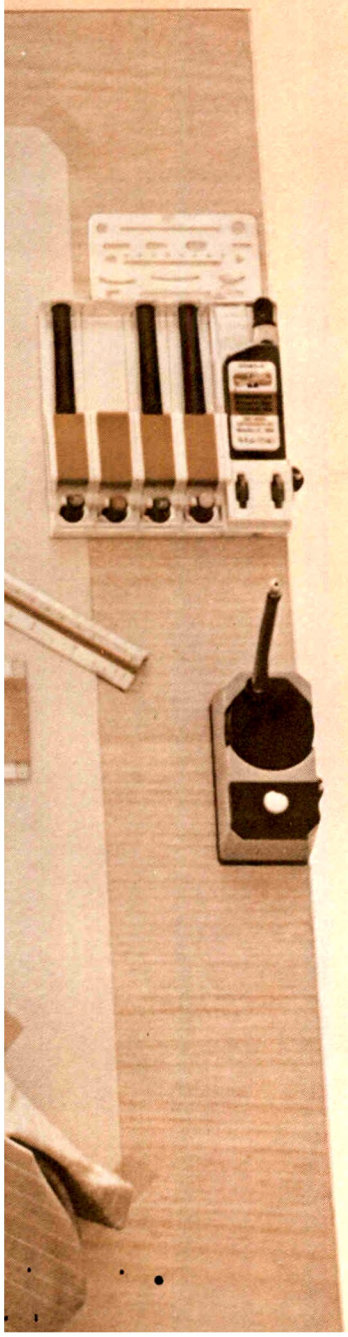
For depressed patients who must function effectively in daily activities...

PAMELOR®

(nortriptyline HCl) NF

25 mg. Capsules

Patients remain alert.



Most depressed patients must function effectively in their daily activities, on the job or at home. For these patients, PAMELOR capsules may be an appropriate therapeutic choice. PAMELOR relieves depression, yet rarely causes daytime drowsiness. As with all antidepressants, however, patients should be cautioned against driving or operating hazardous machinery.

Insomnia of depression begins to improve within a week.

PAMELOR capsules are effective for relieving insomnia, a cardinal symptom of depressive illness. Patients begin to sleep better within the first week of therapy. The full therapeutic effect of PAMELOR is usually observed by the second week.

PAMELOR therapy is well tolerated.

In 90 studies, a total of 818 patients were treated with PAMELOR capsules. Of the patients who improved completely or markedly, over half (54%) had no side effects. Those who experienced side effects most commonly complained of dry mouth.

Indications: For relief of depressive symptoms. Endogenous depressions are more likely to be alleviated than others.

Contraindications: Hypersensitivity. Should not be given concomitantly with MAO inhibitors or within 2 weeks of the use of this drug since hyperpyretic crises, severe convulsions, and fatalities have occurred when similar tricyclic antidepressants were used in such combinations. Cross-sensitivity with other dibenzazepines is a possibility. Contraindicated during acute recovery period after myocardial infarction.

Warnings: Use with caution in patients with cardiovascular disease because of tendency to produce sinus tachycardia and prolong conduction time. Myocardial infarction, arrhythmia, and strokes have occurred. May block antihypertensive action of guanethidine and similar agents. Because of anticholinergic activity, use cautiously in patients with glaucoma or a history of urinary retention. Patients with a history of seizures should be followed closely because the drug is known to lower the convulsive threshold. Great care is required for hyperthyroid patients and those taking thyroid medication because of possible development of cardiac arrhythmia. Caution patients about possibility of impaired mental and/or physical ability to operate a motor vehicle or dangerous machinery. Response to alcoholic beverages may be exaggerated and may lead to suicidal attempts. Safe use during pregnancy, lactation, and women of childbearing potential has not been established and the drug should not be given unless clinical situation warrants potential risk. Not recommended for use in children.

Precautions: Psychotic symptoms may be exacerbated in schizophrenic patients. Increased anxiety and agitation may occur in overactive or agitated patients. Manic-depressive patients may experience shift to manic phase. Hostility may be aroused. Concomitant administration of reserpine may produce a "stimulating" effect. Watch for possible epileptiform seizures during treatment. Use cautiously with anticholinergic or sympathomimetic drugs. Concurrent electroconvulsive therapy may increase hazards associated with nortriptyline HCl. When possible, discontinue drug several days prior to surgery. Potentially suicidal patients require supervision and protective measures during therapy. Prescriptions should be limited to the least possible quantity. Both elevation and lowering of blood sugar levels have been reported.

Adverse Reactions: Note: The pharmacologic similarities among the tricyclic antidepressant drugs require that each of the following reactions be considered when nortriptyline is administered.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric: Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia, panic, nightmares; hypomania; exacerbation of psychosis.

Neurologic: Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alteration in EEG patterns; tinnitus.

Anticholinergic: Dry mouth and rarely, associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis; constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic: Skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight); edema (general or of face and tongue), drug fever, cross-sensitivity with other tricyclic drugs.

Hematologic: Bone-marrow depression, including agranulocytosis; eosinophilia; purpura; thrombocytopenia.

Gastrointestinal: Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black-tongue.

Endocrine: Gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency, nocturia; drowsiness, dizziness, weakness, fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms: Though these are not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

Dosage and Administration: *Usual adult dose*—25 mg. three or four times daily; dosage should begin at a low level and increase as required. As an alternate regimen, the total daily dosage may be given once-a-day. *Elderly and Adolescent*—30 to 50 mg. per day, in divided doses, or the total dosage may be given once-a-day. Doses above 100 mg. per day and use in children are not recommended. If a patient develops minor side effects, the dosage should be reduced. The drug should be discontinued promptly if adverse effects of a serious nature or allergic manifestations occur.

How Supplied: Capsules 10 mg. and 25 mg.; solution 10 mg./5 cc.

Must the MBD child take a controlled drug in school?

Not if he's taking Cylert® (pemoline) CIV 18.75, 37.5, 75 mg tablets

'hildren can be cruel. Their teasing about taking noontime ıedication can cause serious problems for the child with MBD.

Here's how Cylert eliminates this problem:

- Once a day dosage at home
- Eliminates mid-day school dose

In addition, Cylert offers these benefits:

- Avoids ups and downs of drug action brought about by multiple daily dosage
- Control of medication by the parent
- A chewable dosage form
- Less physician paper work (Cylert is in schedule IV)
- Safety and efficacy proven in extensive clinical studies*

*Copy of the Cylert Monograph available to Physicians on written request.

When not to use medication

ylert should not be used for (and will not e effective in) simple cases of overactivity school-age children.

either should it be used in the child who xhibits symptoms secondary to environ- ental factors and/or primary psychiatric disorders, including psychosis.

The physician should rely on a complete history of the child and a thorough description of symptoms from both parents and teacher before postulating a diagnosis of MBD.

ABBOTT

Please see next page for Prescribing Information.

Cylert and Cylert Chewable Tablets

(pemoline)

Prescribing Information

Indications: *MINIMAL BRAIN DYSFUNCTION IN CHILDREN*—as adjunctive therapy to other remedial measures (psychological, educational, social).

Special Diagnostic Considerations: The cause of minimal brain dysfunction (MBD) is unknown. Diagnosis of MBD involves the use of medical, psychological, educational, and social tools, since no single diagnostic test is adequate.

MBD is characterized by chronic moderate to severe hyperactivity, short attention span, distractibility, emotional lability, and impulsivity. Nonlocalizing (soft) neurological signs, learning disability, and abnormal EEG may or may not be present. The diagnosis of MBD must be based upon a complete history and evaluation of the child and not solely on the presence of one or more of these characteristics.

Drug treatment is not indicated for all children with MBD. In the primary therapy of MBD, appropriate educational placement is essential and psychosocial intervention is generally necessary. When these measures alone are insufficient, the decision to prescribe stimulant medication will depend upon the physician's assessment of the chronicity and severity of the child's symptoms. Stimulants are not intended for use in the child who exhibits symptoms secondary to environmental factors and/or primary psychiatric disorders, including psychosis.

Contraindications: Cylert (pemoline) is contraindicated in patients with known hypersensitivity or idiosyncrasy to the drug. (See ADVERSE REACTIONS.)

Warnings: Cylert is not recommended for children less than 6 years of age since its safety and efficacy in this age group have not been established.

Sufficient data on the safety and the efficacy of the long-term use of Cylert in children with minimal brain dysfunction are not yet available.

A temporary suppression of the predicted growth rate (weight and/or height gain) has been reported for children receiving long-term stimulant therapy. A definite causal relationship between stimulant drugs and this finding has not been established.

Precautions: Liver function tests should be performed periodically during therapy with Cylert. The drug should be discontinued if abnormalities are revealed and confirmed by follow-up tests. (See ADVERSE REACTIONS regarding reports of abnormal liver function tests and jaundice.)

Cylert should be administered with caution to patients with significantly impaired hepatic or renal function.

The interaction of Cylert with other drugs has not been studied in humans. Patients who are receiving Cylert concurrently with other drugs, especially drugs with CNS activity, should be monitored carefully.

Cylert failed to demonstrate a potential for self-administration in primates. However, the pharmacologic similarity of pemoline to other psychostimulants with known dependence liability suggests that psychological and/or physical dependence might also occur with Cylert. There have been isolated reports of transient psychotic symptoms occurring in adults following the long-term misuse of excessive oral doses of pemoline. Cylert should be given with caution to emotionally unstable patients who may increase the dosage on their own initiative.

Usage during Pregnancy and Lactation: The safety of Cylert (pemoline) for use during pregnancy and lactation has not been established.

Fertility, reproduction, and teratology studies were conducted in laboratory animals. Pemoline, in doses of 18.75 or 37.5 mg./kg./day, had no effect on the fertility of male or female rats. The drug, when given to pregnant rats (from gestation day 15 through weaning) and to rabbits (from gestation days 6-18) at these same dosage levels, produced no teratogenic or embryotoxic effects, and had no effect on the viability of the young at birth. However, increased incidences of stillbirths and cannibalization were observed when pemoline was given to rats at these dosage levels, beginning 14 days prior to conception.

Adverse Reactions: Insomnia is the most frequently reported side effect of Cylert; it usually occurs early in therapy, prior to an optimum therapeutic response. In the majority of cases it is transient in nature or responds to a reduction in dosage.

Anorexia with weight loss may occur during the first weeks of therapy. In the majority of cases it is transient in nature; weight gain usually resumes within three to six months.

Stomach ache, skin rashes, increased irritability, mild depression, nausea, dizziness, headache, drowsiness, and hallucinations have been reported.

Elevations of SGOT, SGPT, and serum LDH have occurred in patients taking Cylert, usually after several months of therapy. These effects appear to be reversible upon withdrawal of the drug, and are thought to be manifestations of a delayed hypersensitivity reaction. There have also been a few reports of jaundice occurring in patients taking Cylert; a causal relationship between the drug and this clinical finding has not been established.

There have been reports of dyskinetic movements of the lips, face, and extremities occurring with the use of Cylert. Convulsive seizures have also been reported. A definite causal relationship between Cylert and these reactions has not been established.

Mild adverse reactions appearing early during the course of treatment with Cylert often remit with continuing therapy. If adverse reactions are of a significant or protracted nature, dosage should be reduced or the drug discontinued.

How Supplied: Cylert (pemoline) is supplied as monogrammed, grooved tablets in three dosage strengths:

18.75 mg. tablets (white) in bottles of 100 (**NDC** 0074-6025-13)
37.5 mg. tablets (orange-colored) in bottles of 100 (**NDC** 0074-6057-13)
75 mg. tablets (tan-colored) in bottles of 100 (**NDC** 0074-6073-13)

Cylert Chewable is supplied as monogrammed, grooved tablets in one dosage strength:

37.5 mg. tablets (orange-colored)
in bottles of 100 (**NDC** 0074-6088-13)

PLAN AHEAD!!!
Order your 1979 Appointment Book Now !!!

The "week-at-a-glance" Appointment Book, published by the American Psychiatric Association, has been developed over several years to satisfy the needs of as many members as possible. It contains a comprehensive list of addresses and annual meeting dates of all major organizations and agencies of interest to psychiatrists. Members who have not tried this book in the past are urged to do so. It is returnable within 30 days for a full refund if not acceptable. In addition, the name of the physician or hospital can be imprinted on the front cover for $1.00 a copy, providing that the order is received by July 15.

The Pocket Size Appointment Book is also available and can be ordered in combination with the Desk Appointment Book.

Copies will be available September 1978

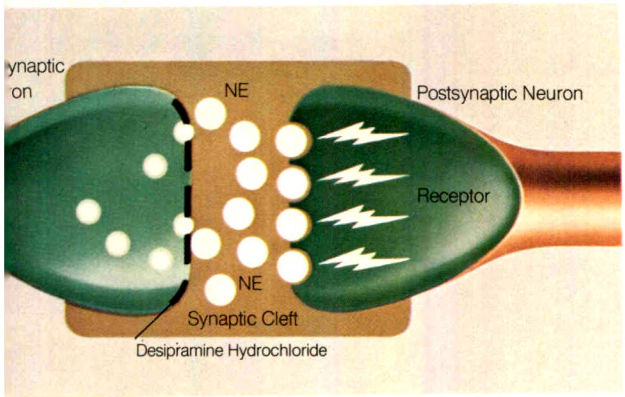
When your patient is clinically depressed...
"...everything I saw was negative."



...consider this potent blocker of norepinephrine re-uptake

The biogenic amine hypothesis states that depression may be associated with a deficiency of specific neurotransmitters—norepinephrine or serotonin—at brain receptor sites.[1] Tricyclics appear to block the re-uptake of specific neurotransmitters. Some tricyclics specifically block the re-uptake of serotonin; others block the re-uptake of norepinephrine.[2] Therefore, if your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic which blocks the re-uptake of a different neurotransmitter.

(Electron micrograph of human synaptic cleft.)

lorpramin®
lesipramine ydrochloride ablets NF)
,50,75,100,150 mg.

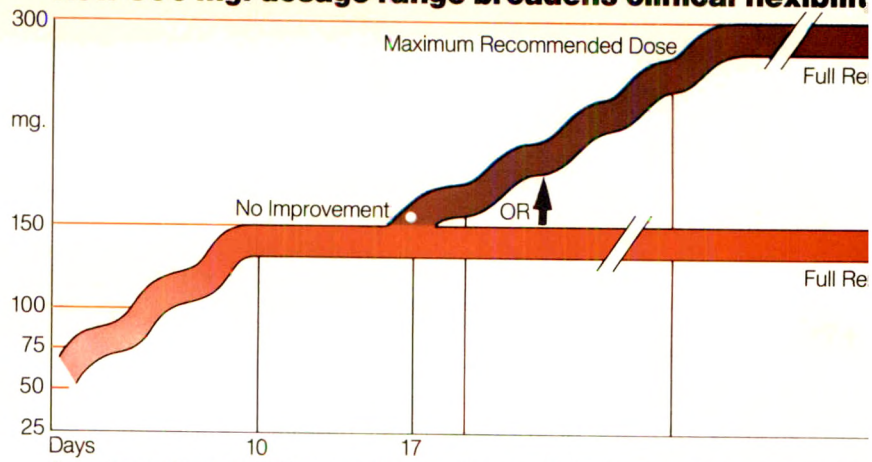
tent blocker norepinephrine re-uptake
cording to current theory[1,3] some clic antidepressants may fail in certain es of depression because they are not iciently potent blockers of norepi- hrine re-uptake. Laboratory studies e shown that desipramine is the most nt inhibitor of norepinephrine ptake.[4] Norpramin may work in some ents when other tricyclic antidepres- ts do not.

onsider it now, onsider it next.

Less anticholinergic activity
(See Warnings section.)
Studies in animals[5] and in normal human subjects[6,7] have shown that desipramine has significantly less anticholinergic activity than amitriptyline or doxepin. The single bond side chain is associated with lower anticholinergic activity than these other leading antidepressants. This may mean:
- less dry mouth
- less blurred vision
- less urinary retention

Helps patients remain calm but active
Norpramin does not usually inhibit normal activity although patients should be cautioned as to driving or operating machinery if drowsiness occurs.

In addition…



Begins to improve sleep patterns within one week in some patients[8]
- Norpramin helps relieve the sleep disturbances that often accompany depression.
- As the depression is relieved, the difficulty in falling asleep, restlessness, and early morning awakening diminish.

Merrell

Now 300 mg. dosage range broadens clinical flexibilit

A maximum dosage of 300 mg. a day, as a single or divided dose, may now be prescrib Norpramin. Since inadequate dosage is thought to be one of the major causes of treatm failure, the new therapeutic range should prove clinically helpful. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

ADVERSE REACTIONS: Note: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enl ment and galactorrhea in the female; increas decreased libido, impotence, testicular swelling; e tion or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered function; weight gain or loss; perspiration, flus urinary frequency, nocturia; parotid swelling; dr ness, dizziness, weakness and fatigue, headache pecia.

Withdrawal Symptoms: Though not indicative of a tion, abrupt cessation of treatment after prolo therapy may produce nausea, headache, and ma

DOSAGE AND ADMINISTRATION: Not recommended fo in children. Lower dosages are recommended for el patients and adolescents. Lower dosages are recommended for outpatients compared to hospita patients, who are closely supervised. Dosage shou initiated at a low level and increased accordir clinical response and any evidence of intoler Following remission, maintenance medication ma required for a period of time and should be at the lo dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 20 per day. In more severely ill patients, dosage ma further increased gradually to 300 mg./day if neces Dosages above 300 mg./day are not recommende

Dosage should be initiated at a lower level increased according to tolerance and clinical resp

Treatment of patients requiring as much as 30 should generally be initiated in hospitals, where re visits by the physician, skilled nursing care, anc quent electrocardiograms (ECG's) are available.

The best available evidence of impending to from very high doses of Norpramin is prolongation QRS or QT intervals on the ECG. Prolongation of th interval is also significant, but less closely corre with plasma levels. Clinical symptoms of intoler especially drowsiness, dizziness, and postural hyp sion, should also alert the physician to the nee reduction in dosage. Plasma desipramine measure would constitute the optimal guide to dosage mor ing.

Initial therapy may be administered in divided d or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescen geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower level increased according to tolerance and clinical resp to a usual maximum of 100 mg. daily. In more severe patients, dosage may be further increased to 150 day. Doses above 150 mg./day are not recommend these age groups.

Initial therapy may be administered in divided d or a single daily dose.

Maintenance therapy may be given on a once- schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a dis sion of symptoms and treatment of overdose.

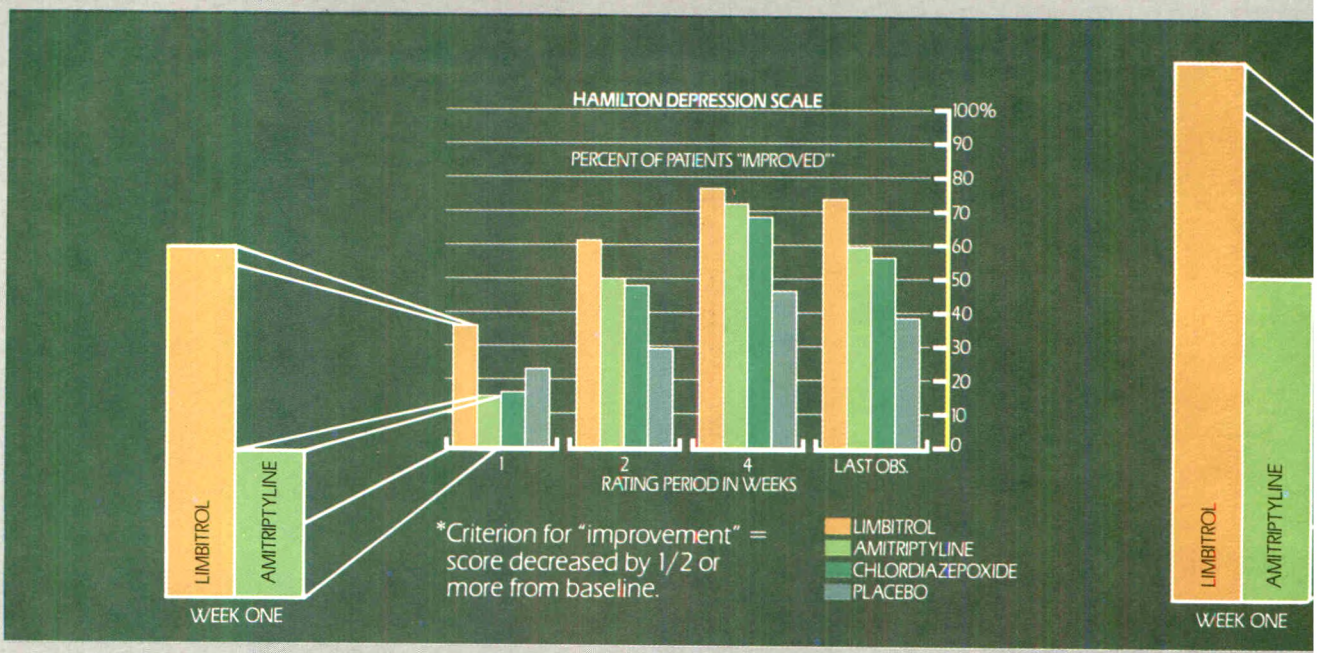
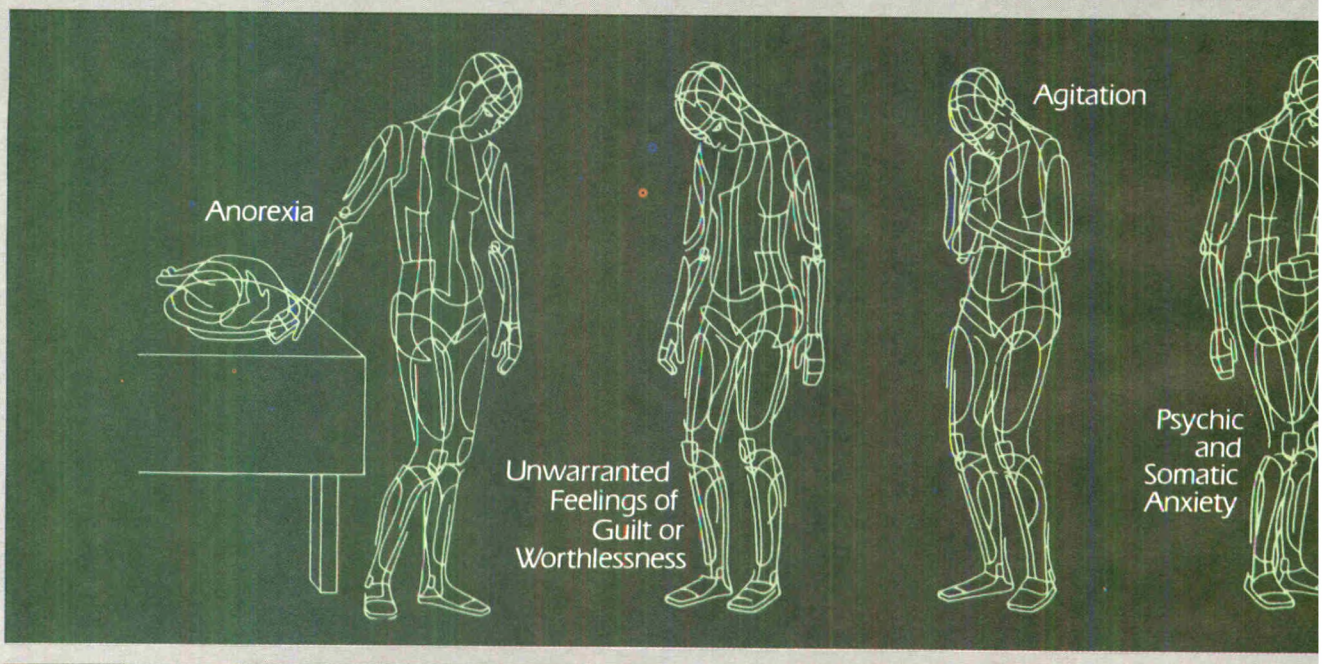
Limbitrol®

Provides the well established antidepressant effect of amitriptyline with the proven antianxiety effect of Librium® (chlordiazepoxide HCl)





For rapid relief of symptoms in moderate to severe depression and anxiety

In a rigidly controlled nationwide multicenter study, when compared to amitriptyline alone, Limbitrol achieved these superior results...

rion for "improvement" =
decreased by 1/3 or
from baseline.

Greater patient improvement

Within the first week—

twice as many patients achieved significant relief—sooner than with amitriptyline alone

omnia, a major target symptom, can relieved sooner by taking advantage he sedative effect of Limbitrol. For ne patients, the larger part or all of daily dose may be given at bedtime.

Better relief of symptoms

Within the first week—

symptom severity was reduced to a greater extent than with amitriptyline alone

As measured by the Hamilton Depression Scale

- insomnia
- psychic anxiety
- somatic anxiety
- agitation
- suicidal ideation
- worthlessness

As measured by the Beck Depression Inventory

- pessimism
- dissatisfaction
- guilt
- social withdrawal
- anorexia

imbitrol®

lets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)
lets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)

r rapid relief of
oderate to severe
pression and anxiety

Greater patient acceptance

- Despite a higher incidence of drowsiness, there was a lower dropout rate due to side effects with Limbitrol than with amitriptyline

(Limbitrol 4%, amitriptyline 13%, chlordiazepoxide 1%)

- The dropout rate due to therapeutic failure was lower with Limbitrol than with amitriptyline

(Limbitrol 2%, amitriptyline 6%, chlordiazepoxide 12%)

ROCHE

How to Initiate and Maintain Therapy

Select dosage strength appropriate for each patient

- Limbitrol 10-25 is recommended for most patients
- Limbitrol 5-12.5 may be indicated for those who do not tolerate higher doses and for elderly patients

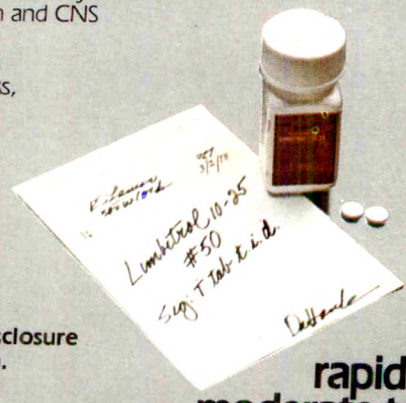
Specify daily dosage based on symptom severity

- An initial dosage of three tablets is recommended
- Dosage may be increased to six tablets or decreased to two tablets daily as necessary
- Once a satisfactory response is obtained, evaluate response, and if necessary, reduce dosage to smallest amount needed to maintain remission

Utilize dosage options to best accommodate individual patient needs

- T.I.D. or Q.I.D., familiar regimens best suited for patients who tolerate medication without undue drowsiness
- Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
- Entire dosage h.s. to take maximum advantage of the sedative effect

How to make each patient an informed patient



1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted or the symptom treated.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under following circumstances

1. Hypersensitivity to benzodiazepines tricyclic antidepressants.
2. Should not be given with an MAO in hibitor. To replace an MAO inhibitor wi Limbitrol, discontinue MAO inhibitor fo minimum of 14 days before cautiously i ing Limbitrol therapy.
3. During the acute recovery phase foll ing myocardial infarction.

Limbitrc

rapid relief
moderate to sev
depression and anxie

LIMBITROL® TABLETS
Tranquilizer–Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

Usage in Pregnancy: **Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage. withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergics: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urir tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression includin agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomasti the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaund alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatme symptomatic and supportive. I.V. administration to 3 mg physostigmine salicylate has been repor to reverse the symptoms of amitriptyline poisonir See complete product information for manifestati and treatment.
Dosage: Individualize according to symptom se and patient response. Reduce to smallest effecti dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bed Single *h.s.* dose may suffice for some patients. L dosages are recommended for the elderly. Limbitrol 10-25, initial dosage of three to four tabl daily in divided doses, increased up to six tablets decreased to two tablets daily as required. Limbi 5-12.5, initial dosage of three to four tablets daily divided doses, for patients who do not tolerate hi doses.
Supplied: Limbitrol 10-25 tablets each containin mg chlordiazepoxide and 25 mg amitriptyline (as hydrochloride salt) and Limbitrol 5-12.5 tablets e containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles 100 and 500; Tel-E-Dose® packages of 100; Prescription Paks of 50.

CHARLES C THOMAS • PUBLISHER

OCIAL CONFLICT AND MENTAL HEALTH SERVICES *by* **obert D. Borgman.** The author integrates social conflict theory ith phenomenological, developmental, and problem-solving techques to provide a singularly effective framework for underanding and intervening in the lives of troubled and troublesome dividuals and families. *'78, cloth-$24.50, paper-$18.50*

MOTIONAL WELL-BEING THROUGH RATIONAL BEAVIOR TRAINING (Rev. 3rd Ptg.) *by* **David S. Goodman.** This ook is a comprehensive study of rational behavior training, a ghly-directive method of teaching people how to increase their ill in reasoning so that they will be better able to deal with the oblems and stresses of daily living. *'78, $9.75, paper*

CIENCE OF PSI: ESP and PK *by* **Carroll B. Nash.** This textbook in short, a comprehensive, nonrepetitive treatment of the entire ience of parapsychology. '78, $16.95

YPNOSIS INDUCTION TECHNICS (4th Ptg.) *by* **Myron Teilbaum.** Phenomena of hypnotism such as regression, hallucinaon, spontaneous anesthesia, amnesia, and posthypnotic action are tailed. *'78, $10.00*

SYCHOLOGICAL TESTS AND SOCIAL WORK PRACTICE: n Introductory Guide *by* **Morton L. Arkava** *and* **Mark E. Snow.** his book concentrates on the interpretation and utilization of sychological test information rather than on test administration. *9, cloth-$8.50, paper-$5.50*

ENSORY CHANGES IN THE ELDERLY *by* **Francis B. Covita.** This book analyzes how the five senses are affected by the ging process. Concrete suggestions for keeping sensory decline to minimum are given. *'78, $11.75*

REATING COMMUNITY ACCEPTANCE FOR HANDIAPPED PEOPLE *by* **Roberta Nelson.** The author defines physal and attitudinal barriers, suggests ways to educate and to elicit pport from the community, and discusses issues in habilitation d rehabilitation. *'78, $14.75*

EX-RELATED COGNITIVE DIFFERENCES: An Essay on heory and Evidence *by* **Julia A. Sherman.** Biological theories, cluding purported sex differences in brain lateralization and reted sociocultural determinants are discussed. *'78, cloth-$16.25, aper-$12.25*

EHAVIOR THERAPY IN CLINICAL PRACTICE: Decision aking, Procedure and Outcome *by* **Ernest G. Poser.** The text xplores specific fears, physical expressions of social withdrawal, cially disapproved behavior, and current problems in behavior odification. *'77, $15.75*

ASIC PRINCIPLES OF LONG-TERM PATIENT CARE: Develping a Therapeutic Community *by* **Charles H. Kramer** *and* **annette R. Kramer.** By incorporating ideas from a variety of edical, sociological and psychological disciplines, the authors ow how to build a therapeutic community in extended care facilies. *'76, $22.75*

UMANIZING ORGANIZATIONAL BEHAVIOR *edited by* **H. eltzer** *and* **Frederic R. Wickert.** The nature, extent and social gnificance of humanizing organizational behavior are considered. *6, $34.25*

NVOLUNTARY TREATMENT OF THE MENTALLY ILL: he Problem of Autonomy *by* **Michael Alfred Peszke.** The author ggests that programs designed to meet the needs of the mentally l be based on the right of each person to his or her own autonmy. *'75, $12.50*

UMAN BEHAVIOR AND BRAIN FUNCTION *edited by* **arvey J. Widroe.** Minimal cerebral dysfunction in children and dolescents, aggression control defects, schizophrenia, manic deressive psychosis, and behavior disorders secondary to cerebral teriosclerosis are discussed. *'75, $8.50*

SENSORY-MOTOR DYSFUNCTION AND THERAPY IN INFANCY AND EARLY CHILDHOOD *by* **Delmont Morrison, Patricia C. Pothier** *and* **Katy Horr.** Topics covered include assessment and therapy, the relationship between sensory-motor and emotional development, and interventions for early-occurring emotional disturbances. *'78, $14.75*

CASE STUDIES IN CLINICAL AND SCHOOL PSYCHOLOGY *by* **Ralph F. Blanco** *and* **Joseph G. Rosenfeld.** Case studies detail the symptoms, causes, treatment, and follow-up of conditions ranging from learning disabilities to multiple handicaps. *'78, $11.50*

DRUGS AND THE ELDERLY: Social and Pharmacological Issues *edited by* **David M. Petersen, Frank J. Whittington** *and* **Barbara P. Payne.** Eighteen prominent professionals provide a comprehensive overview of the subject as well as a thorough review of the available literature. *'78, $23.75*

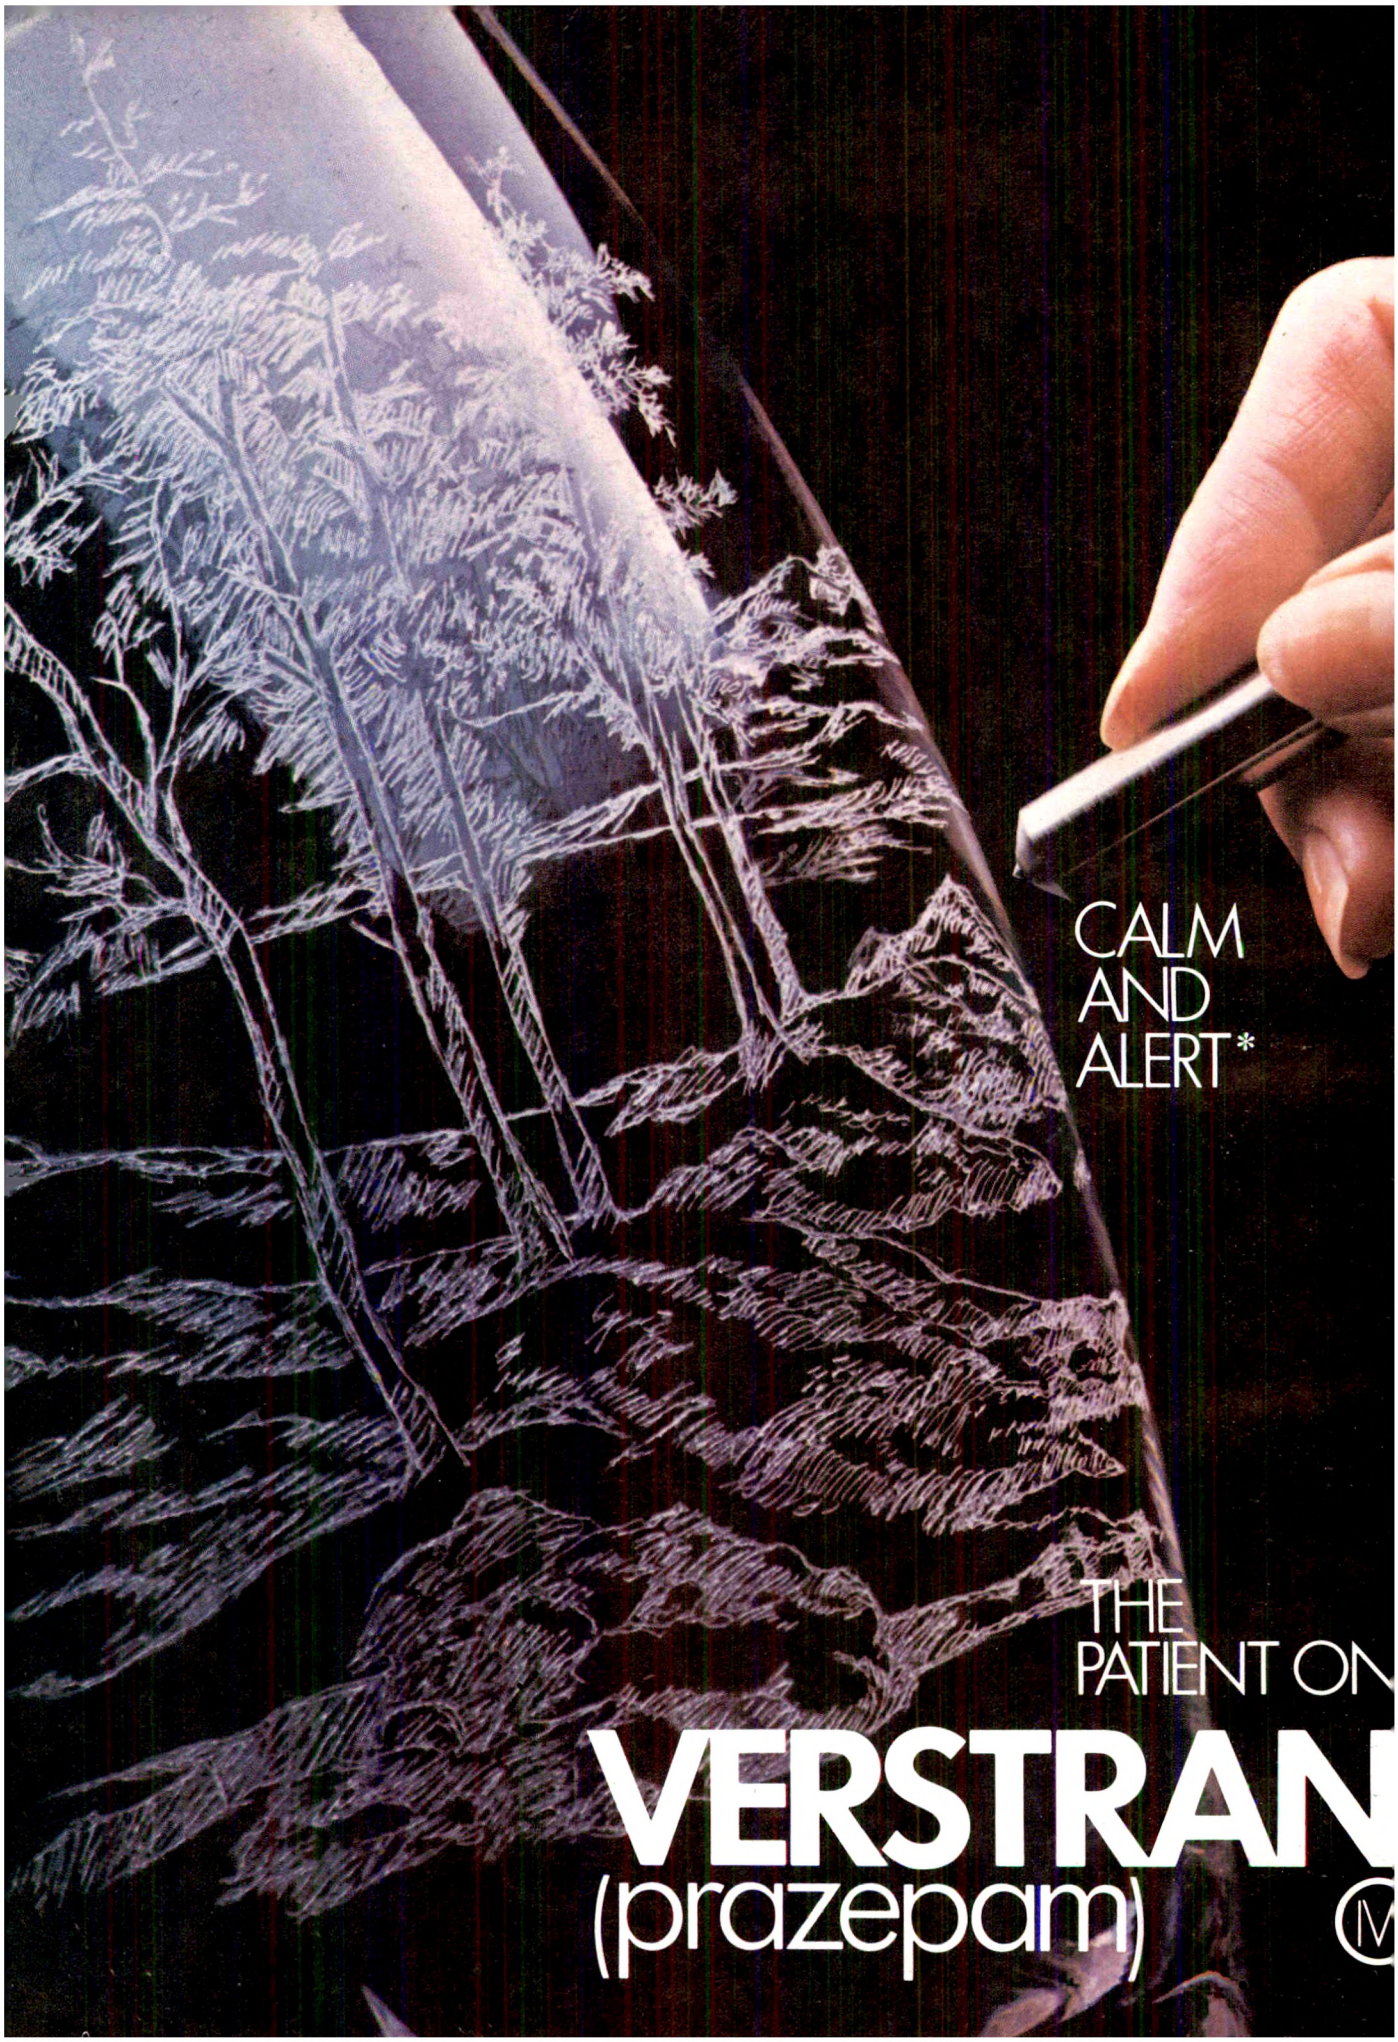
CANINE BEHAVIOR: A History of Domestication; Behavioral Development and Adult Behavior Patterns; Neurophysiology; Psychobiology, Training, Inheritance, Early Experience and Psycho-Social Relationships; Experimental Neuroses and Spontaneous Behavioral Abnormalities; Congenital Anomalies and Differential Diagnosis of Neurologic Disease (3rd Ptg.) *by* **M. W. Fox.** *'78, $8.95*

THE DIAGNOSIS AND TREATMENT OF ALCOHOLISM (2nd Ed.) *by* **Gary G. Forrest.** Current treatment strategies discussed are: psychotherapy, behavior therapy, Alcoholics Anonymous, residential treatment, marital and family therapy, and disulfiram maintenance. *'78, cloth-$17.50, paper-$12.95*

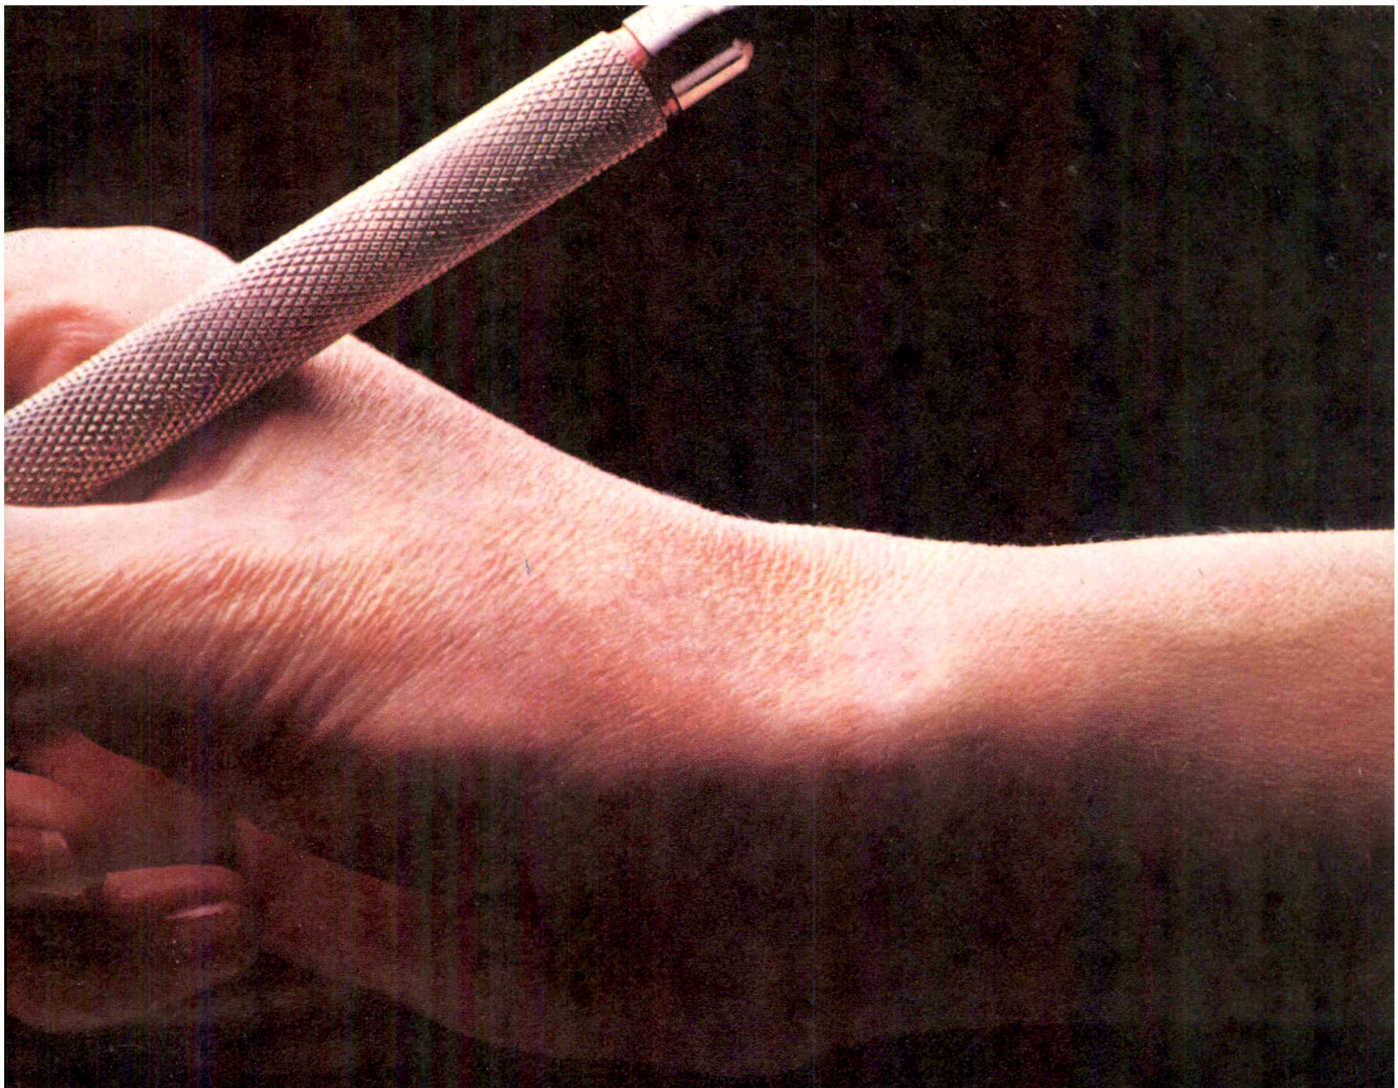
MEDICAL WRITING: The Technic and the Art (4th Ed., 2nd Ptg.) *by* **Morris Fishbein.** The text explains the steps one should follow in preparing a paper for various audiences in various situations. Technical advice is offered. *'78, $11.50*

STRESS AND RELAXATION: Application to Dentistry *by* **Donald R. Morse** *and* **Merrick L. Furst.** Stress control methods — relaxation through meditation and hypnosis, cardiovascular-enhancing exercises, psychological coping techniques — are delineated. *'78, $14.75*

ASSERTIVE TRAINING FOR WOMEN (2nd Ptg.) *by* **Susan M. Osborn** *and* **Gloria G. Harris.** The authors review ways in which women are socialized to be submissive and dependent. They evaluate the usefulness of traditional and alternative psychotherapeutic approaches. *'78, cloth-$12.25, paper-$9.25*



THE POWER OF POSITIVE REINFORCEMENT: A Handbook of Behavior Modification *by* **Judith Elbert Favell.** Definition and specification of target behavior, measurement techniques, data representation, and application of behavior modification are covered. *'77, $11.25*



CRISIS INTERVENTION AND HOW IT WORKS *by* **Romaine V. Edwards.** This book shows the reader how to elicit the solution to a crisis from the client experiencing the difficulty. Specific situations are discussed. *'77, $9.25*

BEHAVIORAL SCIENCE IN CLINICAL MEDICINE *by* **Stewart Wolf** *and* **Helen Goodell.** This text illustrates the importance of understanding the patient as a person before the practice of medicine, diagnosis and treatment can be effective. *'76, $16.75*

A PRIMER ON SCHOOL MENTAL HEALTH CONSULTATION *by* **Morton I. Berkowitz.** This guidebook presents the why, when, where and how of consultation in the schools. *'75, $11.50*

THE EMOTIONALLY DISTURBED CHILD: A Book of Readings (2nd Ptg.) *compiled and edited by* **Larry A. Faas.** Behavior modification, management and discipline, and the prevention of emotional disturbance are covered. *'75, $16.75*

CALM
AND
ALERT*
THE
PATIENT ON
VERSTRAN
(prazepam)

Smooth, consistent anxiolytic action is the reason.

Proven efficacy

- Effective symptomatic relief of anxiety, whether psychic or somatic in origin
- Therapeutic response achieved with first dose
- Verstran—a suitable antianxiety alternative to diazepam

Established safety

- Virtually no drowsiness* in most Verstran patients (less than 10%)
- Other side effects, if present, are minimal†
- Verstran is appropriate concomitant therapy in most somatic disorders‡
- No accumulation after steady state is reached

Dosage versatility

- The simplicity of a single-strength 10-mg scored tablet, for easy titration and improved patient compliance
- The flexibility of *once daily*§ dosage
- The option of a *b.i.d.* dosage regimen, gradually adjustable within a range of 20 to 60 mg/day

As with all CNS-acting agents, patients should be cautioned against driving, drinking, or engaging in hazardous activities.

Data on file, Warner/Chilcott Medical Department.

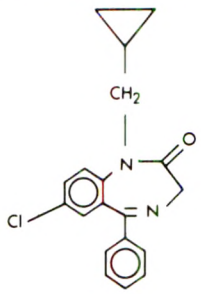
See package insert.

At bedtime.

Before prescribing, see complete product information on the following page.

TO ENHANCE
PATIENT
RESPONSIVENESS
CONSIDER

VERSTRAN



(prazepam)

Ⓝ

VERSTRAN® (prazepam) Ⓝ

Caution: Federal law prohibits dispensing without prescription.

Description: Verstran (prazepam), a benzodiazepine derivative, is identified chemically as 7-chloro-1-(cyclopropylmethyl)-1,3-dihydro-5-phenyl-2H-1,4-benzodiazepin-2-one. The molecular weight is 324.8 and the structural formula is as follows:

Clinical Pharmacology: Studies in normal subjects have shown that Verstran (prazepam) has depressant effects on the central nervous system. Oral administration of single doses as high as 60 mg and divided doses up to 100 mg t.i.d. (300 mg total daily dose) were without toxic effects.

Single oral doses of Verstran in normal subjects produced peak blood levels at 6 hours postadministration, with significant amounts still present after 48 hours. Verstran was slowly absorbed over a prolonged period, rather constant blood levels were maintained, and excretion was prolonged. The mean half-life of prazepam measured in subjects given 10 mg t.i.d. for one week was 63 (±15 s.d.) hours before and 70 (±10 s.d.) hours after multiple dosing — a nonsignificant difference. Human metabolism studies showed that prior to elimination from the body, prazepam is metabolized in large part to 3-hydroxyprazepam and oxazepam.

Indications: Verstran (prazepam) is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

The effectiveness of Verstran (prazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

Contraindications: Verstran (prazepam) is contraindicated in patients with a known sensitivity to the drug and in those with acute narrow angle glaucoma.

Warnings: Verstran (prazepam) is not recommended in psychotic states and in those psychiatric disorders in which anxiety is not a prominent feature.

Patients taking Verstran should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery, including motor vehicles.

Because Verstran has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, including phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants. The effects of alcohol may also be increased.

Physical and Psychological Dependence: Withdrawal symptoms similar in character to those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepine drugs. These symptoms include convulsions, tremor, abdominal and muscle cramps, vomiting and sweating. Addiction-prone individuals, such as drug addicts and alcoholics, should be under careful surveillance when receiving benzodiazepines because of the predisposition of such patients to habituation and dependence.

Precautions:

Use in Pregnancy and Lactation:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. Verstran (prazepam) a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug. In view of their molecular size, Verstran and its metabolites are probably excreted in human milk. Therefore, this drug should not be given to nursing mothers.

In those patients in whom a degree of depression accompanies the anxiety, suicidal tendencies may be present, and protective measures may be required. The least amount of drug that is feasible should be available to the patient at any one time.

Patients taking Verstran for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed. Hepatomegaly and cholestasis were observed in chronic toxicity studies in rats and dogs.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

Pediatric Use: Safety and effectiveness in patients below the age of 18 have not been established.

Adverse Reactions: The side effects most frequently reported during double-blind placebo-controlled trials employing a typical 30 mg divided total daily dose and the percent incidence in the Verstran (prazepam) group were: fatigue (11.6%), dizziness (8.7%), weakness (7.7%), drowsiness (6.8%), lightheadedness (6.8%), and ataxia (5.0%). Less frequently reported were: headache, confusion, tremor, vivid dreams, slurred speech, palpitation, stimulation, dry mouth, diaphoresis, and various gastrointestinal complaints. Other side effects included: pruritus, tr
sient skin rashes, swelling of feet, joint pains, vari
genitourinary complaints, blurred vision, and s
cope. Single nightly dose, controlled trials of varia
dosages showed a dose-related incidence of th
same side effects. Transient and reversible aber
tions of liver function tests have been reported,
have slight decreases in blood pressure and increa
in body weight.

These findings are characteristic of benzodiazepi
drugs.

Overdosage: As in the management of overdosa
with any drug, it should be borne in mind that mu
ple agents may have been taken.

If vomiting has not occurred spontaneously,
should be induced. Immediate gastric lavage is a
recommended. General supportive care, includi
frequent monitoring of the vital signs and close obs
vation of the patient, is indicated. Hypotensi
though unlikely, may be controlled with Levophe
(levarterenol bitartrate) or Aramine® (metarami
bitartrate). Caffeine and Sodium Benzoate Injecti
USP, may be used to counteract central nervous syst
depressant effects.

Dosage and Administration: Verstran (prazepam)
administered orally in divided doses. The usual da
dose is 30 mg. The dose should be adjusted gradua
within the range of 20 to 60 mg daily in accordar
with the response of the patient. In elderly or deb
tated patients it is advisable to initiate treatment a
divided daily dose of 10 mg to 15 mg. (See Prec
tions.)

Prazepam may also be administered as a sin
dose daily at bedtime. The recommended starti
nightly dose is 20 mg. The response of the patient
several days' treatment will permit the physician
adjust the dose upward or, occasionally, downwarc
maximize antianxiety effect with a minimum of dc
time drowsiness. The optimum dosage will usua
range from 20 to 40 mg.

Drug Interactions: If Verstran (prazepam) is to
combined with other drugs acting on the central n
vous system, careful consideration should be given
the pharmacology of the agents to be employed. T
actions of the benzodiazepines may be potentiated
barbiturates, narcotics, phenothiazines, monoami
oxidase inhibitors or other antidepressants.

If Verstran is used to treat anxiety associated w
somatic disease states, careful attention must be pc
to possible drug interaction with concomitant medi
tion.

How Supplied: Verstran (prazepam) 10 mg light blu
scored tablets in bottles of 100 (N 0047-0276-51) a
1000 (N 0047-0276-60).

STORE BETWEEN 59°–86° F (15°–30° C).

Precise, easy-to-use

The B24 III SERIES Electroconvulsive THERAPY INSTRUMENTS

Designed to provide the physician with the ultimate in precision dosage, with consistency of output assured by the following:

- *Line Voltage Compensation*—Automatically adjusts variations in line voltage.
- *Pre-programmed Voltage Selection*—Offers a choice of 11 voltage levels, from 70 to 170 volts.
- *Automatic Treatment Timing*—Will adjust from 0.1 second to 1.0 second, with or without Glissando
- *Current Output Indicators*—During treatment current flow is clearly indicated.

Exclusive Patient Test Module allows a complete systems integrity check prior to treatment. 100% solid state circuitry assures clinical accuracy and dependability.

The B24 III series meets all requirements for Underwriters Laboratories—UL 544, Standards for Medical and Dental Equipment.

For complete information, phone toll-free, or write Hittman Medcraft.

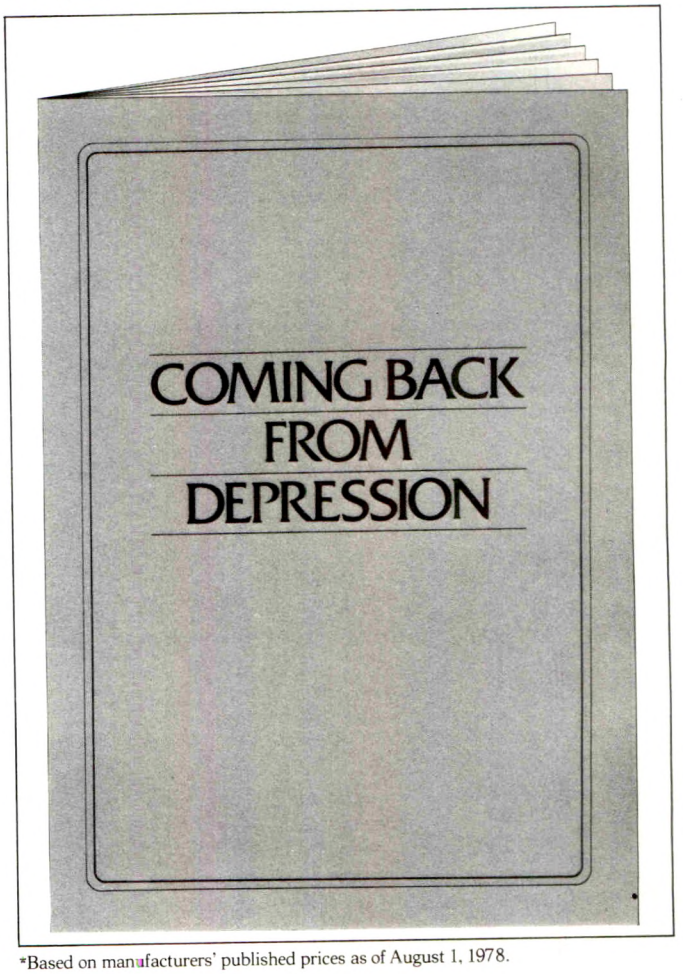
You know what to expect from antidepressant therapy;



...but does your patient?

ou know that it generally takes two or ree weeks for tricyclic therapy to begin orking in depression...and that some de effects may be encountered. But, in all kelihood, your patient doesn't.

To lessen the time you spend in explana-on and to increase patient compliance, e've prepared a special patient informa-on booklet in conjunction with the intro-uction of Amitid—a high quality, low cost mitriptyline from Squibb. Entitled "COM-G BACK FROM DEPRESSION," this booklet ffers encouragement to depressed pa-ents, helps you explain the basic facts out depression and outlines some of the ings to be expected during therapy, the od *and* the bad.

You can get a supply of this carefully ritten booklet simply by sending a equest on your letterhead to E. R. Squibb Sons, Inc., Department 31, P.O. Box 000, Princeton, New Jersey 08540. And ou can save your patients significant mounts of money by specifying Amitid on l your amitriptyline prescriptions.

Amitid is available in five separate rengths, and is bioequivalent to the lead-g brand of amitriptyline. Amitid offers all ne known clinical advantages of amitriptyline—relieving a wide range of depression-associated symptoms. Yet Amitid is priced considerably lower than other leading brands;* bringing savings that should help ease the burden of depression for patients...just a little bit more!

*Based on manufacturers' published prices as of August 1, 1978.

Introducing

Amitid™

Amitriptyline Hydrochloride Tablets USP

lowers the cost, not the quality, of antidepressant therapy

Please see following page for brief summary.

SQUIBB®

Amitid™ (Amitriptyline Hydrochloride Tablets USP)

DESCRIPTION: Amitriptyline hydrochloride is a dibenzocycloheptadiene derivative available for oral administration as FILMLOK® tablets (FILMLOK is a Squibb trademark for veneer-coated tablets).

INDICATIONS: For relief of symptoms of depression alone or accompanied by anxiety. Endogenous depression is more likely to be alleviated than are other depressive states.

CONTRAINDICATIONS: Contraindicated in patients with a history of hypersensitivity to amitriptyline. Do not administer concomitantly with a monamine oxidase (MAO) inhibitor since hyperpyretic crises, severe convulsions, and deaths occurred when tricyclic antidepressants and MAO inhibitors were administered simultaneously. When an MAO inhibitor is to be replaced by amitriptyline, allow 14 days to elapse after discontinuation of the former and then initiate amitriptyline cautiously and gradually increase dosage until optimum response is achieved. Amitriptyline is not recommended for use during the acute recovery phase following myocardial infarction.

WARNINGS: Amitriptyline may block antihypertensive action of guanethidine or similarly acting drugs. Use with caution in patients with history of seizures and (because of atropine-like action of amitriptyline) in patients with history of narrow-angle glaucoma (even average doses may precipitate an attack), increased intraocular pressure, or urinary retention. Closely watch patients with cardiovascular disorders since, in addition to having caused myocardial infarction and stroke, tricyclic antidepressants (including amitriptyline) particularly with high dosage have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time. Close supervision is required when amitriptyline is given to hyperthyroid patients or those on thyroid medication. Amitriptyline may impair mental and/or physical abilities required for performance of hazardous tasks such as operating machinery or driving a motor vehicle. Bear in mind that in patients who may use alcohol excessively the potentiation may increase the danger inherent in any suicide attempt or overdosage.

Usage in Pregnancy: Safe use during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women who may become pregnant, weigh the possible benefits against the possible hazards to the mother and child. Animal reproduction studies have been inconclusive, and clinical experience has been limited.

Usage in Children: At the present time, not recommended for patients under 12 years of age because of lack of experience with use in children.

PRECAUTIONS: Schizophrenic patients may develop increased symptoms of psychosis; patients with paranoid symptomatology may have an exaggeration of such symptoms; manic depressive patients may experience a shift to the manic phase. In these circumstances the dose of amitriptyline may be reduced or a major tranquilizer may be administered concurrently.

Closely supervise and carefully adjust dosage in concomitant use with anticholinergic or sympathomimetic drugs, including combination of epinephrine and local anesthetics. Paralytic ileus may occur with concomitant use of tricyclic antidepressants and anticholinergic-type drugs. Caution is advised if used concurrently with large doses of ethchlorvynol since transient delirium has been reported when one gram of that drug and 75 to 150 mg of amitriptyline HCl were administered. Amitriptyline may enhance response to alcohol and the effects of barbiturates and other CNS depressants. The possibility of suicide in depressed patients remains during treatment and until significant remission occurs. Potentially suicidal patients should not have easy access to large quantities of the drug. Prescriptions should be written for the smallest amount feasible. Limit concurrent administration of this drug and electroshock therapy to patients for whom it is essential since the hazards associated with such therapy may be increased. Discontinue this drug, when possible, several days before elective surgery. Both elevation and lowering of blood sugar levels have been reported. Use amitriptyline with caution in presence of impaired liver function.

ADVERSE REACTIONS: NOTE: A few of the adverse reactions listed below have not been reported with this specific drug, but each of the reactions should be considered when administering amitriptyline because of pharmacological similarities among tricyclic antidepressants.

Cardiovascular: Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, and stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness; tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; and syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth, blurred vision, disturbance of accommodation, increased intraocular pressure, constipation, paralytic ileus, urinary retention, and dilatation of the urinary tract. *Allergic:* Skin rash, urticaria, photosensitization, and edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis, leukopenia, eosinophilia, purpura, and thrombocytopenia. *Gastrointestinal:* Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, parotid swelling, and black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male, breast enlargement and galactorrhea in the female, increased or decreased libido, and elevation and lowering of blood sugar levels. *Other:* Dizziness, weakness, fatigue, headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, drowsiness, and alopecia. *Withdrawal Symptoms:* Abrupt cessation of treatment after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

For full prescribing information, consult package insert.

HOW SUPPLIED: Available for oral administration in tablets providing 10, 25, 50, 75, and 100 mg amitriptyline hydrochloride. The 10, 25, and 50 mg tablets are available in bottles of 100 and 1000. The 75 and 100 mg tablets are available in bottles of 100.

SQUIBB®

He has five years to fight for your life

He is an American Heart Association Established Investigator, funded for five years to work on some phase of cardiovascular disease. He and his associates are researching ways to recognize a heart attack before severe damage occurs.

His ultimate goal is to decrease the present toll from cardiovascular diseases. Of the four Americans that die every minute this year from all causes, two will die from these diseases.

He is one of over 1,400 scientists supported by the American Heart Association who are fighting for your life.

But we need more money for more research that may produce earlier detection and better methods of treatment and prevention of cardiovascular diseases.

When a Heart Association volunteer asks for your money, think of the 1,400 scientific investigators. Help them fight for your life.

Please give generously to the American Heart Association

The Office of Continuing Medical Education
Albert Einstein College of Medicine

Announces Two Courses

Clinical Neurology For Psychiatrists:

Part 1 and Part 2

Under the Direction of

David M. Kaufman, M.D.

Department of Neurology
Montefiore Hospital and Medical Center

Part 1. Friday, Saturday, and Sunday; March 23, 24 and 25. This course, designed for psychiatrists preparing for the written part of the **American Board of Psychiatry and Neurology**, will consist of a series of lectures, videotaped demonstrations, and a practice written examination.
30 hours of Category 1 credit will be awarded.

Part 2. Saturday and Sunday; October 6 and 7. the continuation, a course for candidates for the oral section of the Board, will review major neurological disorders by presenting audiovisual demonstrations and practice examinations.
20 hours of Category 1 credit will be awarded.

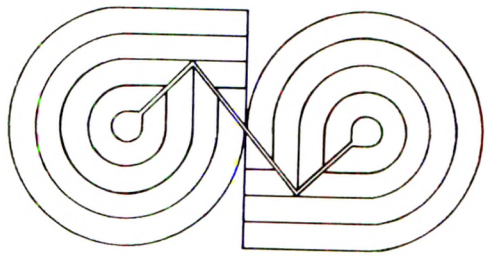
The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.



Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

An equal opportunity employer. All our programs are accredited by the appropriate Councils of the Joint Commission on Accreditation of Hospitals.

PKSAP-III

PSYCHIATRIC KNOWLEDGE AND SKILLS SELF-ASSESSMENT PROGRAM

CONTINUOUS OFFERING

PKSAP-III is again available. The Program, initially available to physicians in Spring/Summer, 1977, will differ in that central scoring services will not be provided. Each registrant will receive the question booklets, the Reference guidebook containing the correct answers and bibliography, a score worksheet, and the Performance Data Report, which will facilitate self-scoring, follow-up reading and study at the participant's convenience. For further program details, the Bulletin of Information, is available upon request to the APA, Office of Education.

To register, remit the appropriate fee with this application form to the APA, PUBLICATIONS SALES. PLEASE MAKE CHECKS PAYABLE TO APA, PKSAP-III.

ı consideration beyond :fficacy alone...

nfrequent akathisia ınd other disabling :xtrapyramidal effects...

ıe rapidly rising readmission rate among discharged sychotic patients is mainly due to noncompliance with ıtipsychotic drug therapy. And this, in turn, may be rgely attributed to disabling extrapyramidal side effects, otably akathisia.[1]

though extrapyramidal effects are characteristic of anti-sychotic agents in general, with Mellaril (thioridazine) ıch effects are infrequent. Adding an antiparkinsonian gent—which can cause its own side effects—can usually e avoided. Mellaril (thioridazine) is contraindicated in ıtients with severe hypotensive or hypertensive eart disease.

trapyramidal Effects of Selected ıtipsychotic Agents*[2]

DRUG	EXTRAPYRAMIDAL EFFECTS
Chlorpromazine	Moderate
Perphenazine	High
Prochlorperazine	High
Fluphenazine	High
Acetophenazine	Moderate
Trifluoperazine	High
Chlorprothixene	Moderate
Thiothixene	Moderate
Haloperidol	High
MELLARIL® (thioridazine)	Low

ased on antipsychotic dosage ranges

Mellaril® thioridazine)

ABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP
ONCENTRATE: 100 mg per ml

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.
Store and dispense Concentrate below 86°F; use tight, amber glass bottle. Just prior to administration, Concentrate may be diluted with distilled water, acidified tap water, or suitable juices; preparation and storage of bulk dilutions is not recommended.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.
It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

HE AMERICAN JOURNAL OF PSYCHIATRY

hort-Term Dynamic Psychotherapy

Y JUDD MARMOR, M.D.

hort-term dynamic psychotherapy is rooted in ychoanalytic theory. The author traces the storical background of brief psychotherapy, cusing on the contributions of Freud, Ferenczi, ank, and Alexander and French, and then presents a nthesis of contemporary views. Selection criteria for itients who can benefit from short-term therapy, and e techniques used, are discussed. Similarities to and fferences from crisis intervention techniques are inted out. The trend of the future can be expected to toward shorter-term therapies, but given the esent state of psychiatric knowledge, long-term erapy will still be necessary for many patients.

E ARE LIVING in the midst of a major psychoerapeutic revolution in this second half of the twentih century. New therapies of all kinds have emerged astounding numbers, some scientifically based, oths reverting to the magical, mystical, and religious ots that were the precursors of scientific psychotherpy. At the same time the development of third-party ayers, together with the imminence of some form of ational health insurance, places psychiatrists under essure to find shorter, more broadly applicable, and ore efficient techniques of therapy or risk exclusion om these programs for fiscal reasons. As a conquence, we can anticipate that the briefer techniques group therapy, behavioral therapy, and family therpy will emerge more strongly in the years ahead. The ct is, however, that the vast majority of American sychiatrists are still heavily committed to a one-to-ne model of dynamic psychotherapy (1). Therefore, e greatest need to develop more time-effective approaches is in this area.

ceived Sept. 18, 1978; revised Oct. 16, 1978; accepted Nov. 7, 78.

r. Marmor is Franz Alexander Professor of Psychiatry, University Southern California School of Medicine, 2025 Zonal Ave., Los ngeles, Calif. 90033.

HISTORICAL BACKGROUND

Brief dynamic psychotherapy is rooted in the psychoanalytic tradition. Its fundamental insights and its basic theoretical principles would not have been possible were it not for the ground-breaking discoveries of Sigmund Freud. Actually, some of the earliest psychoanalytic treatments conducted by Freud tended to be of quite short duration. Bruno Walter, the conductor, described in his autobiography (2) a successful six-session therapeutic experience he had with Freud in 1906. Jones (3, pp. 79–80) related that in 1908 Freud was able to get at the psychodynamic roots of the composer Gustav Mahler's potency problem with his wife and relieve it in a single four-hour session. Even Freud's early didactic analyses were almost all of relatively short duration, ranging from several months to about one year (3, pp. 31–32, 161–162). As the goals of psychoanalysis became more ambitious, however, and its theoretical superstructure grew more complex, analytic treatments began to increase in length to such an extent that in his later years Freud pessimistically concluded that some of them were becoming interminable (4).

Many of the early analysts were aware of and troubled by this trend, but the first psychoanalytic pioneer to methodically explore modifications in psychoanalytic technique for the purpose of shortening the length of classical analysis was Sandor Ferenczi, who, around 1918, began to experiment with a technique that he called "active therapy." Ferenczi (5) claimed that in so doing he was merely following Freud's lead. He referred to a paper that Freud had presented at the Budapest International Congress in 1918 (6) in which Freud stated that in certain cases of phobia or obsessional neurosis it is sometimes necessary, in order to advance the therapy, to institute active measures to induce the patient to face the phobia or anxiety. Ferenczi also pointed out that activity as a technique was inherent in the psychoanalytic process because every interpretation that is given constitutes an interference with the patient's psychic transactions of that moment

0002-953X/79/02/0149/07/$00.60 © 1979 American Psychiatric Association

and thus facilitates the appearance of thoughts that otherwise might not have become conscious.

Ferenczi experimented with various types of activity in the psychoanalytic situation in an effort to overcome what he called a "stagnation of the analysis." Some of his techniques were restrictive or pressuring (e.g., forbidding masturbation or insisting that patients control certain body movements or other actions Ferenczi deemed to be in the service of "unconscious resistance"). Other interventions were loving or indulgent, based on the theory that the analyst as a parent surrogate was thus making amends for the rejections and traumata that the patient may have suffered from his own parents.

Ferenczi's "reparative" efforts included hugging, kissing, and nonerotic fondling of his patients. When Freud heard of these, he wrote Ferenczi the now famous letter (7) expressing his very dim view of these activities and predicting prophetically that they would eventually lead to greater excesses on the part of other therapists. He wrote,

> A number of independent thinkers in matters of technique will say to themselves: Why stop at a kiss? . . . Bolder ones will come along who will go further. . . . The younger of our colleagues will find it hard to stop at the point they originally intended, and God the Father Ferenczi, gazing at the lively scene he has created will perhaps say to himself: Maybe after all I should have halted in my technique of motherly affection *before* the kiss.

Ferenczi subsequently abandoned these particular techniques, but he never gave up his efforts to develop a more active approach to analytic therapy.

Ferenczi's efforts brought him into early collaboration with Otto Rank, who had been pursuing similar approaches independently. Ferenczi and Rank worked together for a number of years on evolving various modifications of technique, culminating in 1925 in their publication of the slender but seminal volume *The Development of Psychoanalysis* (8). In this volume they pointed out that early in the history of psychoanalysis "splendid cures . . . were effected, sometimes in a few days or weeks" (p. 52) but that as analytic theory and knowledge expanded analyses became longer and longer. They attributed this to a need for "discovering afresh in every single case the psychological and theoretical knowledge derived from analysis" (p. 59) and to turning every analysis into a proving ground for analytic theory. Ferenczi and Rank characterized this as "making the disastrous mistake of neglecting the actual [therapeutic] task for the sake of the psychological interest" (pp. 24–25).

They pointed out that the technique of psychoanalytic treatment, although dependent on psychoanalytic theory, need not and indeed should not remain tied to the "investigative" methods out of which the theory evolved. In this context they criticized an undue preoccupation in therapy with the historical past and emphasized the paramount importance of focusing on the present analytic situation and its transference implications. Anticipating Franz Alexander's concept of the "corrective emotional experience," Ferenczi and Rank asserted that the goal of psychoanalysis "is to substitute by means of the technique, effective factors of experience for intellectual processes" (p. 62). They expressed the conviction that greater understanding of these practical principles of technique would ultimately make it possible to "shorten and simplify psychoanalytic treatment."

In some ways Otto Rank may well be the most important historical forerunner of the brief dynamic psychotherapy movement. His concept of the trauma of birth (9), although biologically and psychodynamically dubious, laid the groundwork for the subsequent recognition of the predominant importance in personality development of the pre-oedipal years, particularly the early mother-child relationship. When Rank published his views, however, the primary emphasis in psychoanalytic theory was on the oedipal period and castration anxieties rather than on the pre-oedipal period and the more basic separation anxieties. Rank's views were vigorously attacked by Freud's psychoanalytic contemporaries because they were correctly perceived as threatening the fulcrum of Freud's theories at that time.

It is unfortunate that the issue of disloyalty to Freud has cast a heavy shadow over the value of Rank's achievements. Looking back from the vantage point of our present knowledge of the importance of pre-oedipal relationships in personality development as well as the nuclear importance of separation and individuation in emotional maturation, we can now perceive that Rank was the prime theoretical precursor of these developments, without in any way denigrating the later creative contributions of people like Rene Spitz (10), Margaret Mahler (11), or John Bowlby (12).

As his ideas evolved, Rank himself began to play down the importance of the birth trauma itself and to recognize that the issue of separation and individuation was really the core problem. He made its working through the central focus of his psychotherapeutic method. It is not surprising, therefore, that Rank was the first analyst to attribute major importance to the setting of a time limit for the analytic process to promote an earlier therapeutic focus on the problem of separation. However, Rank was not the first analyst to experiment with setting a termination date in advance. Freud did this in 1912 in his analysis of the "Rat Man," which he published in 1918 as "From the History of an Infantile Neurosis" (13). Although Freud recognized the usefulness of this technical device, he never made it a cardinal point in his analytic technique. Rank, on the other hand, considered the setting of a time limit central to the therapeutic work and the issue of separation and individuation critical to the process of adaptation and maturation in all of human existence. Thus at a very early point in Rank's therapy the analytic work became centered on the anxieties and conflicts surrounding separation and terminatic

id the entire therapeutic process was foreshortened. recent years Mann has made this technique the fo- l point of his approach to time-limited psychothera- y, but, surprisingly, he made only a brief and pas- ng reference to the work of Rank in his book (14).

It is also interesting, in the light of current develop- nts in brief psychotherapy, to take a second look at nk's concept of "will therapy" (15). Rank empha- ed the importance of mobilizing the patient's "will" the course of therapy and claimed that by so doing e therapeutic process could be facilitated. If we were substitute for the word "will" the more modern m "motivation," we would find that Rank was ying something that has been emphasized by all dern theorists about short-term dynamic psycho- rapy, namely, the overwhelming importance in- hieving a favorable therapeutic outcome of a strong tivation to change on the part of the patient. In this nnection it is noteworthy that four of the seven cri- ia for motivation to change used by Sifneos (16) in lecting patients for brief psychotherapy employ the ncept of willingness (i.e., willingness to actively par- ipate in the treatment situation, willingness to un- rstand oneself, willingness to change, and willing- ss to make reasonable sacrifices in terms of time and s). What is willingness in this context but the ability mobilize one's "will" toward a particular objective?

When, some 20 years after Ferenczi and Rank's ntributions, Alexander and French came out with eir important and seminal volume on psychoanalytic rapy (17), they were frank to admit that their work as "a continuation and realization of ideas first pro- sed by Ferenczi and Rank." The work of Alexander d French stands on its own merits, however. Their lume was the culmination of seven years of research d investigation into the development of shorter ap- oaches to psychotherapy that had been carried out the Chicago Institute of Psychoanalysis.

Alexander, the prime mover in this research, had for ars been puzzled by what he called the "baffling dis- epancy" between the length and intensity of psycho- alytic treatment and the degree of therapeutic suc- ss. He began his investigations by questioning the lidity of the following traditional psychoanalytic gmas: 1) that the depth of therapy is necessarily pro- rtionate to the length of treatment and frequency of terviews, 2) that therapeutic results achieved by a latively small number of interviews are necessarily perficial and temporary but results of more pro- ged therapy are necessarily more stable and pro- und, and 3) that prolongation of an analysis is justi- d on the grounds that the desired therapeutic results e more likely to be achieved than through briefer chniques. None of these traditional assumptions oved to be justified.

In the course of their research, Alexander and his lleagues experimented with the frequency of inter- ews, the optional use of the chair or couch, long or ort interruptions of therapy preparatory to termi- tion, and the combination of psychotherapy with drug or other therapy. They also sought to learn how to control and manipulate the transference relationship to fit the particular psychodynamics of each case. The first and most important principle that evolved from these studies, that of flexibility, seems obvious today, but it was revolutionary in an era dominated by the conviction that the standard psychoanalytic method was the optimum method of therapy for most neurotic patients. Alexander insisted that in psychotherapy as in all medical therapy the physician should adapt his technique to the needs of the patient. "Only the nature of the individual case," he said, "can determine what technique is best suited to bring about the curative processes" (17, p. 26).

Alexander also pointed out that in many instances daily interviews prove to be antitherapeutic because they gratify the patient's dependent needs more than is desirable. He questioned the therapeutic value of promoting regression and argued that it should be "a general principle in all psychotherapy to attempt to check this regressive tendency from the very beginning of the treatment" (17, p.30). This principle was subsequently strongly advocated by Sandor Rado (18).

As one way of heightening the emotional intensity of interviews with patients Alexander recommended consciously manipulating the frequency of visits. He felt this was an effective technique for controlling the transference relationship, limiting regression, preventing the development of overdependency on the therapist, and fostering autonomy. He also advocated interruptions of treatment as another way of increasing the emotional intensity and efficiency of the therapeutic process. Interruptions, by virtue of their ability to test the patient's capacity for self-reliance and for more effectively coping with his life situation, could also be used as preparatory indicators enabling both therapist and patient to arrive at a mutually agreed on termination point.

Like Ferenczi and Rank, Alexander placed great emphasis on the emotional experiences of the patient in relation to the therapist, specifically on what he called the "corrective emotional experience," in which the patient is reexposed under the more favorable circumstances of the transference relationship to emotional situations that he could not handle in the past.

Alexander asserted that in order to know what new emotional experiences are necessary to achieve therapeutic results, the therapist must understand not only the patient's current psychodynamics but also the genetic development of his difficulties. In this respect Alexander's technique differs decisively from that of Rank, who tended to minimize the importance of such genetic understanding. The more precise this understanding, according to Alexander, the more adequately the therapist can provide the proper corrective emotional experience. Therefore, he felt that the therapist's reactions had to be planned on the basis of these dynamic insights.

Although Alexander's views were violently attacked

by most of the classical psychoanalysts of his time, by now the principles he elucidated have become part of the daily working equipment of almost every psychiatrist and psychoanalyst. It is fair to say that Alexander more than any other modern psychoanalyst is responsible for leading the way toward the application of psychoanalytic principles to more active and shorter dynamic psychotherapy. As a consequence of his germinal work, an increasing number of psychoanalysts began to practice more flexibly during the years following World War II. Psychoanalysts began to see their patients less frequently than the traditionally mandated four or five times weekly, often working with them face to face and, in general, entering into more active communicative transactions with them than the more passive classical model required.

In more recent years, as the demand for psychotherapy has widened to encompass greater and greater segments of the population, the pressures to clarify our therapies and sharpen our skills in the application of psychodynamic theory to briefer forms of psychotherapy have continued to increase. Beginning with the 1960s, a number of psychoanalysts both in the United States and abroad have responded to this challenge by picking up where Alexander and French left off. Malan (19, 20), Wolberg (21), Bellak and Small (22), Sifneos (16), Balint and associates (23), Mann (14), and Davanloo (24) are but a few of the individuals who have contributed significantly to the theory and technique of short-term psychotherapy. In the pages that follow I shall attempt to present a synthesis of their views that will reflect the present state of the art in short-term dynamic psychotherapy.

SELECTION CRITERIA

Short-term dynamic psychotherapy rests on two basic substructures, selection and technique. Each of these is of equal importance. Not all patients are equally suitable for short-term dynamic psychotherapy, but a substantial proportion of those who are ordinarily considered suitable for longer-term analytic procedures are equally suitable for the shorter-term approach.

At the very outset of the selection process it is important to underline the necessity for a good history and a psychodynamic diagnosis. By a psychodynamic diagnosis I do not mean placing the patient into a formal nosologic category but, rather, carefully evaluating both the inner and outer forces that contribute to the patient's psychopathology. Inasmuch as short-term dynamic psychotherapy involves an uncovering and searching out of relevant unconscious intrapsychic factors, the therapist looks for qualities in the patient that will indicate his capacity to work effectively in this way. The following are the most important of these qualities: 1) evidences of ego strength (e.g., intelligence, level of educational achievement, sexual adjustment, type of work, ability to assume responsibility), 2) at least one meaningful interperso relationship in the past, indicating a capacity for ba trust, which is essential in the psychotherapeu process, 3) the ability to interact with the therapist the first session (i.e., the capacity to form a positi transference), 4) the ability to think in psychologi terms (i.e., the ability to accept interpretation or, a is sometimes called, the capacity for insight, which usually tested in the initial interview by making a t tative interpretation and evaluating the patient's sponse to it), and 5) the ability to experience feelir (i.e., the degree to which the individual seems to be touch with his own emotions).

The above five qualities are essential factors in selection of patients for any form of dynamic psycl therapy, long-term as well as short-term. Two ad tional selection factors are particularly relevant to a essential for a short-term psychotherapeutic approac The first of these is the existence of a focal conflict. T therapist should be able in the first interview or two, most, to identify a central conflictual problem arou which most of the patient's difficulties revolve. S neos (16) has stated that this focal conflict must oedipal, but this view is not shared by others. For ample, the focal conflict can also be a dependence-dependence conflict, a sibling rivalry situation, o difficulty in coping with object loss.

The other selection factor of prime relevance short-term therapy is the existence of a clear-cut a strong motivation to change. Malan (19, 20) prope emphasized that the issue is not simply one of the tient's wish to get rid of his symptoms but of an ceptance of the fact that in the process some ba change in adaptational patterns may be necessary.

As already noted, with the exception of the last tw all of these selection criteria are not very differ from the criteria that are usually applied in decid whether or not a patient is suitable for classical p choanalytic therapy. However, these selection crite are not necessarily indicative of the depth of exist psychopathology. Most contemporary workers in field agree that short-term dynamic psychotherapy c be used with patients who might be described as re tively "sick" as well as for those with relatively mi problems. Patients with a wide variety of personal disorders and psychoneuroses as well as those w transitional crises may be suitable for short-term namic psychotherapy provided they fulfill the sel tion criteria. The critical issue is not diagnosis so mu as the possession of certain personality attributes p the existence of a focal conflict and a high degree motivation.

TECHNIQUE

In considering the technique of short-term dynan psychotherapy it is first necessary to emphasize t there are certain common denominators in all psycl dynamic therapies. I have described these in de

sewhere (25–27) and shall merely summarize them re: 1) a release of tension (catharsis) in a setting of pe and expectation of help, 2) a constructive pa-nt-therapist relationship (therapeutic alliance) based i both unconscious factors (transference factors) as ell as the real qualities that both patient and therapist ing to their transactions, 3) cognitive learning based i interpretations (insight), 4) operant conditioning sed on overt and/or covert indications of approval or sapproval from the therapist that move the patient in e direction of "mental health" (an additional facet of is operant conditioning is the existence of corrective notional experiences in which the therapist reacts fferently and more constructively to the patient than d significant authority figures in the patient's past), identification with the therapist in which the patient sually unconsciously) models himself after the thera-st, incorporating some of the latter's value systems d/or behavioral patterns, 6) elements of suggestion d persuasion, either covert or overt, which are pres-t in all psychotherapies, 7) some aspects of practice d rehearsal of new adaptive techniques and their neralization, sometimes called "working through" "reality testing," all in a setting of consistent emo-nal support from the empathic therapist.

Given these general factors common to all dynamic erapies, how does short-term dynamic psychothera-differ from other therapies? Four factors that are ecific to the short-term technique can be identified. rst, the patient is always seen sitting up, facing the erapist. Although this factor is essential to short-rm dynamic psychotherapy, it is, of course, present many longer-term dynamic therapies as well. Therefore, it is not as unique as the other three factors are. It important, however, for creating a structure in hich a more active transactional process can occur an would be possible with the patient on the couch.

Second, brief therapy always involves setting a time nit. This is a unique and important element in all ort-term psychotherapies. Setting a time limit is essential for the process, and its importance cannot be veremphasized. Mann (14) has discussed the meaning time in psychotherapy in eloquent philosophical rms. From a purely clinical standpoint, however, ree fundamental consequences can be identified as riving from this technical maneuver. First, the set-ng of a time limit places a central emphasis from the ry beginning of the therapy on the issues of separa-n and individuation. This colors the entire therapeu-process from beginning to end and creates an en-ely different set of expectations than in long-term erapy, where the patient is told at the outset that the ngth of therapy is open-ended, unpredictable, or may on for a year or two or more. Second, not only is e issue of separation and individuation relevant, if t central, to the problem presented by most patients, t putting it in the forefront of the therapeutic tech-que reflects a basic respect for and encouragement of e patient's capacity to be autonomous. This counters e patient's impulse to see himself as helpless, inadequate, and in need of dependent support. Third, the very process of termination constitutes a therapeutic act that tends to encourage the patient's independence and self-confidence. This is not to deny that the initial response of most patients to approaching termination is one of anxiety and often of regression. Nevertheless, the firm and steady insistence on a termination date and the working through of separation anxieties is critical to the process of short-term dynamic psychotherapy.

The issue of how many sessions should be involved is still unsettled among short-term psychotherapists. Mann sets an arbitrary and fixed limit of 12 sessions, but Sifneos, Malan, Wolberg, and Davanloo are rather more flexible, varying the number of visits from 15 to 40, depending on the severity of the patient's problem as well as his ego-adaptive capacities. For most patients, somewhere between 20 and 30 visits seems to be quite satisfactory. It has been my own practice after termination to leave the door open for a follow-up visit after three or six months, if the patient desires. This removes the element of finality from the separation process and softens its impact, but the majority of patients given such an opportunity do not find a need for it. Indeed, they tend to feel better as time goes on.

The third specific feature of short-term dynamic psychotherapy is the persistent focus throughout therapy on the core conflict and the refusal to permit defensive digressions from that central focus. This in turn leads to the fourth major factor, the activity of the therapist, an essential feature of short-term therapy. This activity has two major and significant psychodynamic elements. First, it is a reflection of the therapist's interest in and concern for the patient and the therapist's wish to be helpful, which are important therapeutic factors. Second, insisting on adhering to the central focus and actively discouraging digressions maintains a high level of therapeutic tension and interaction throughout the therapy more effectively than the traditional "abstinence" patterns of classical psychoanalysis. Sifneos called this technique "anxiety provoking," and it often is.

It should be emphasized that such activity does not mean that the therapist is being directive. On the contrary, the therapist follows essentially the nondirective line of traditional psychoanalytic therapy. The activity consists of persistent confrontations and interpretations and, by means of these confrontations, of the discouragement of regression. Whenever possible, Menninger's "triangle of insight" (28) is used in offering cognitive interpretations; that is, the therapist tries to link interpretations to the historical past, to the patient's present life situation and interpersonal relationships, and to the transference relationship in the therapeutic situation. Active transference interpretations and the bringing out of negative feelings as well as positive ones constitute an essential part of the technique of short-term dynamic psychotherapy.

The emphasis on transference interpretation and on the acquisition of insight clearly demonstrates the

close link between short-term dynamic psychotherapy and classical psychoanalytic theory. As I have indicated elsewhere (26), it is questionable that insight in and of itself has the specific therapeutic effect that most psychoanalysts attribute to it, but it nevertheless serves as a powerful reinforcement to all of the other factors that play a role in the psychotherapeutic process.

COMPARISON WITH CRISIS INTERVENTION

The question is often raised as to how short-term therapy differs from crisis intervention. It may be useful in this regard to distinguish emergency care, crisis intervention, and short-term dynamic psychotherapy, which in a sense represent different points on a continuum of psychiatric intervention. Emergency care is concerned with the provision of immediate relief or help to a person who has decompensated in the face of internal or external stress and is totally unable to cope with the situation. In crisis intervention one is dealing with an individual who is in danger of decompensating from internal or external stress and is coping poorly. The goal of crisis intervention is to reduce or remove the stress situation and/or to help the patient deal with it more effectively.[1] In short-term dynamic psychotherapy we are dealing with individuals in conflict, not necessarily in crisis, although a crisis situation may be involved. The goal in short-term dynamic psychotherapy is primarily on modifying the patient's coping abilities and only secondarily on relieving stress.

It is evident from these definitions that there are no sharp lines of demarcation among these modes of approach. Each can merge into the other. Emergency treatment may proceed from the provision of immediate relief to an effort to reduce the precipitating stress situation, and in crisis intervention it is often necessary to help the patient develop more effective coping mechanisms to deal with the presenting stress situation as well as future ones. To the extent that crisis intervention emphasizes the modification of coping mechanisms it moves closer to short-term dynamic psychotherapy.

The differences are primarily in terms of emphasis. Crisis intervention is usually of shorter duration and limited to five or six sessions, and dynamic psychotherapy is usually of longer duration. The primary goal of crisis intervention is the restoration of homeostasis. A secondary goal is to improve the patient's adaptive capacity when necessary. The basic goal of short-term dynamic psychotherapy is to improve the patient's coping abilities. The termination point of crisis intervention is when the crisis is resolved. The ter point of short-term dynamic therapy is not dic the resolution of the crisis. Crisis intervention i a more supportive approach than does short-t namic psychotherapy. It can also be more dire short-term dynamic therapy, the approach i but nondirective. Crisis intervention deals o the here and now; short-term dynamic psych includes the exploration of the past to illumi present. Finally, crisis intervention may invol riety of other techniques (e.g., family therap therapy, and dealing with the social netwo short-term dynamic psychotherapy is esser one-to-one approach. However, it may well be lessons learned from short-term dynamic psyc py will find increasing application in conjoint family, and group therapies as time goes on.

INDICATIONS FOR LONGER-TERM PSYCHOTHERAPY

The foregoing does not imply that longer-t namic psychotherapy will no longer be nece indicated. Given the present state of our kn the substantial number of people now seen in psychotherapy who do not meet the selectio for the short-term approach will continue to longer-term therapeutic relationships. These include individuals with more seriously impai integrative capacities, particularly the mor character disorders, and borderline syndro every psychiatrist knows, some patients ma tenuous symbiotic relationship with a psycho for most of their lives in order to be able to functioning.

THEORETICAL OBJECTIONS

The opposition of traditional psychoanalys short-term therapeutic model has been base preconception that in order to be deep, therap be long. Indeed, when in the course of psycho therapy patients improved quickly their impr was usually derogated as a transference cure o into health. The assumption was that the ther inevitably incomplete and that sooner or late tient would be back. However, this often did cur. The reason for the faulty assumption was misconception of the traditional psychoanaly el, namely, that it was a closed-system mode trast to the open-system model of contempor chiatric thought. The closed model posited th all aspects of the patient's libidinal fixations conscious conflicts were worked through the sooner or later lead to a recurrence of s atology. Open-system thinking recognizes abling a patient to function more effectively in ular area leads not only to heightened self-est

[1]Some crisis theorists divide crisis therapy into two categories: crisis support, which focuses on the patient's current problems and/or relief of symptoms, and crisis intervention, which deals with the patient's adaptive and maladaptive coping mechanisms in the crisis situation. The latter technique clearly merges into short-term dynamic psychotherapy and differs from it primarily in being of shorter duration and crisis oriented.

...lso to positive feedback from the environment. These ...hanges, both from within and from without, can mod-...y the internal psychodynamic system without having ...) work everything through.

The classical method of psychoanalysis arose as a ...illiantly innovative research technique created by ...reud to explore the furthermost corners of the uncon-...ious. Phenomenology Associated with Depressed Moods in Adolescents

BY SUBHASH C. INAMDAR, M.D., GREGORY SIOMOPOULOS, M.D., MICHAEL OSBORN, M.D., AND EDGARDO C. BIANCHI, M.D.

The authors studied phenomenology associated with depressed moods in 30 adolescents within a semi-structured interview format using defined symptom items. The results suggest that while there is some symptomatic similarity between adolescent depression and depression in adults, there are many differences that warrant more cautious comparison and further study.

THE VERY EXISTENCE of depression in children has been challenged, but its presence in adolescence has often been presumed. Systematic and detailed studies of affective disorders in adolescents are seldom found (1) while studies of those disorders in children are not so rare. Of the several approaches to adolescent depression, one major viewpoint is that depression like that seen in adults is not possible before adolescence and that late adolescence is the specific phase when this adult picture emerges (2). A second viewpoint, which is presumably based on the belief that there are hidden dynamic similarities in adult depression and childhood and adolescent depressive phenomena, uses terms such as "depressive equivalents" (3) and "masked depression" (4) rather than a phenomenologic definition.

Toolan (3) subsumes under the category "depressive equivalents" a wide variety of symptoms: psychosomatic symptoms, eating and sleeping disturbances, boredom and restlessness, delinquent behavior, and promiscuity. Glaser (4) described "masked depression" as including school phobias and learning difficulties.

Poznanski and Zrull (5) criticized the above terms as being sweepingly inclusive and questioned whether "the depressive side of the equation is even observed." Rie (6) criticized the concept of depressive equivalents along similar lines. He noted that a demon strable connection between the concept of depressio and the behavior considered a depressive equivaler had not been established. He stated that "the use c the term depression demands the identification of th essential nature of the disorder which remains ir variant regardless of the variety of manifestations b which it is recognized."

At present we know of only one clinical descriptiv study (1) that has defined the nature of depressive phe nomena in adolescence; most other studies of adoles cents are based on clinical impressions (7) or case re ports (8). Hudgens (1), in a study of psychiatric dis orders in 110 adolescent inpatients (aged 12–19 admitted to the Washington University Medical Cen ter, reported on the symptomatology of 19 adolescent given a definite diagnosis of depression. Fourteen oth er adolescents who did not fulfill the criteria for th definite diagnosis were called "undiagnosed, most lik depression." The research group at Washington Uni versity is active in the area of diagnostic criteria an has initiated attempts to reduce further the ambiguity of diagnostic criteria for psychopathology in adults b suggesting the use of defined symptom items in struc tured psychiatric interviews (9).

It was the purpose of this study to describe wha adolescents experience in the whole range of phenom ena traditionally linked to childhood and adolescen depression. In this way one could hope at the least t delineate depressive phenomena of adolescence for a specific population and at most to define a form o forms of adolescent depression and to then make clini cal comparisons with defined adult entities.

METHOD

Thirty patients aged 12–18 were selected from thos referred to the Inpatient Adolescent Service of th New York University-Bellevue Hospital Center Twenty patients were aged 12–15 years and 10 patient were aged 16–18. The median age was 15.

The cases were selected as follows: The psychiatri staff identified patients they thought had "depresse moods" and the investigators then applied the criteri listed below.

1. Report of depressed mood as a major psycho pathological feature and confirmation of this in th semi-structured interview.

Received Aug. 18, 1977; revised Nov. 23, 1977; accepted Jan. 10, 1978.

Dr. Inamdar is Assistant Clinical Professor and Dr. Bianchi is Associate Clinical Professor, Department of Psychiatry, New York University Medical Center, 550 First Ave., New York, N.Y. 10016, where Drs. Siomopoulos and Osborn were Fellows in Child and Adolescent Psychiatry when this work was done. Dr. Siomopoulos is now Director, Department of Psychiatry, Greek Air Force Hospital, Athens, Greece, and Dr. Osborn is Associate Attending Psychiatrist, Harlem Hospital Center, New York, N.Y. Dr. Inamdar is also Unit Chief, Adolescent Outpatient Services, and Dr. Bianchi is Director, Adolescent Services, Bellevue Psychiatric Hospital, New York, N.Y.

0002-953X/79/02/0156/04/$00.45 © 1979 American Psychiatric Association

2. Absence of schizophrenia, mental retardation, ganic brain syndrome, or major medical illnesses rsonality disorders were not excluded).

Weitzel and associates (10) thought a free-form non-stematic approach to the clinical interview increased risk of overlooking important areas of inquiry. A riety of self-assessment scales, rating scales, and uctured interviews have been developed to over-me the problem of unstructured interviews. These struments were all judged to have limitations (9), and y have been used mainly with adults. The addition-problems of modification and use of such in-uments with younger adolescents would be consid-ible.

We used a semi-structured interview format. The in-view began with a brief introduction to the purpose the study. A few open-ended questions were posed out the present state of the patient in order to en-nce responsivity to the exploration of affective tes. The interview then proceeded to a list of ap-oximately 50 items on a schedule that evolved from urvey of the literature on depression in children and olescents. The adolescents were evaluated jointly teams of two psychiatrists (S.I. and G.S., S.I and .O.) who used an interviewer/observer design.

The duration of scale administration ranged from 50 90 minutes, with an average of about 1 hour. The ms were asked in fixed sequence, but the inter-ewer allowed room for elaboration and for probing ibiguous responses. Definitions of symptom items re designed to enable interviewers to decide what nstituted affirmative responses. Most of the major ms were defined on the basis of a glossary of terms ed by Wing and associates in the Present State Ex-ination (11), a structured-interview instrument. ms not used by Wing were included and defined, g., running away and diminished school perform-ce.[1]

We included all possible features of depressive phe-mena previously noted as being present in child-od or adolescent depression. However, we ex-ided phenomena that involved inferences from be-vior which could not be assessed in the interview .g., insatiable affection-seeking [12]), as well as char-teristics drawn from data about children in pro-nged psychoanalytic contact (e.g., "therapist diffi-lty in making sustained contact" or "tendency to gress to oral passivity" [13]).

We attempted to make the schedule as comprehen-ve as possible to avoid missing any significant phe-menologic details. In doing so, we intentionally in-ided partially overlapping categories. Because fur-er elaboration was sought on many items, the terview protocols were rich in detail about patients' bjective experiences.

opies of this schedule and scoring instructions are available on equest from the authors.

RESULTS

Table 1 lists the symptoms commonly associated with depressive moods in this study and their prevalence in a study of adolescent inpatients by Hudgens (1) and a study of adult inpatients by Woodruff and associates (14). These two studies, carried out at different times at the same center, were chosen for comparison because they covered a range of symptomatology similar to that in our study. We included any symptom that occurred in at least 50% of any study group and that could be compared with the present study. Seven items in the present study that had no comparison figures in the other studies were also included. It should be noted that interpretations of the comparisons are limited by the lack of operational definitions of symptoms in the other studies. A symptom was considered present in a patient if there was inter-observer agreement. Specific agreement was high (94%). All of the adolescents selected for this study had depressed moods by virtue of the sample selection criteria, whereas the percentage in the comparison studies was slightly less.

Examination of the table reveals that the inclusion criteria selected a group of patients who had some symptom similarity and who experienced many of the depressive features seen in adults. However, we did not find the following symptoms noted in adults by Woodruff and associates (14): restlessness, pacing and hand wringing, agitation, motor retardation, feelings of persecution, delusions of guilt, hopelessness, and delusions at the time of examination. Affective hallucinations, defined as hallucinations with content congruent with a depressed mood, were seen in two subjects in our study (7%). Except for these two, none of our adolescent subjects had the severe symptomatology seen in the adults studied by Woodruff and associates. Hudgens did not report the presence of these symptoms reported by Woodruff and associates or of two symptoms that could be considered important in a study of adolescents: diminished school performance and running away.

Items related to sexuality, such as promiscuity and diminished libido, while rated, were considered difficult to assess within our study design and therefore were thought to be possibly unreliable for comparison. The subjects were reticent about discussing sex, and determination of diminished libido, which entails the establishment of a baseline of sexual activity, was even more difficult in a group with reportedly irregular sexual contacts.

The interview protocols were rich in such details as precipitating circumstances, length of episodes, and circumstances that could terminate the affective state, so we attempted to formulate a composite clinical picture for this population. We included symptoms that were present in more than 50% of the sample.

These adolescents had experienced depressed moods as a major psychopathological feature for a period of a few months to several years. The date of onset was

TABLE 1
Prevalence (in Percents) of Symptoms Associated with Depression

Symptom Items	Adolescents: Current Study (N=30)	Adolescents: Hudgens (1) (N=19)	Adults: Woodruff and Associates (14) (N=54)
Depressed mood	100	95	93
Loss of interest	77	79	89
Loneliness	53	—	—
Feels unloved	53	—	—
Apathy, boredom	90	—	—
Loss of pleasure	83	—	—
Suicidal ideation	77	84	41
Suicidal acts	60	68	11
Poor concentration	70	84	93
Thoughts slowed	37	—	69
Memory disturbance	30	53	—
Self-depreciation (worthlessness)	57	63	74
Social withdrawal	63	—	—
Irritability	33	42	67
Diminished school performance	73	—	—
Running away	57	—	—
Insomnia (delayed sleep, early waking)	57	74	61
Loss of appetite-weight loss	40	53	78
Subjective anergia (tired all day)	30	58	57
Tired upon awakening	53	—	31
Diminished libido	7	—	50
Somatic symptoms (headaches, abdominal pain, muscle aches, dizziness, nausea, constipation)	37	—	74

difficult to ascertain accurately. Some patients could mark the onset by relating it to an important incident, such as a death in the family at a specific age, but others felt that their depressed moods started so gradually that the time of onset could not be defined precisely. Therefore, although it is important, age at onset was not determined.

It is extremely important to note that most of the adolescents looked sad *only* when they were talking about their sad moods. These moods were not transient, ephemeral states that could be considered normative. Although episodic, they were intense, disabling, and associated with many other symptoms. Despite this, the majority of these patients did not specifically complain of depression as a symptom for which they sought relief. The nature, extent, and chronicity of the depressed moods and associated symptoms were revealed only by systematic inquiry. Depressive moods were precipitated primarily by external events and lasted from a few hours to a day or two. Most subjects viewed their depressive moods as stemming from conflict with a significant other and therefore did not see a need for therapeutic intervention.

The depressed moods of these adolescents were typically associated with apathy and boredom, loss of interest, and loss of pleasure in activities that were usually enjoyable. During their depressed moods many the adolescents were socially withdrawn. These associated symptoms lasted from a few hours to a day two and thus matched the duration of the depressed moods. However, during these periods, a close friend could terminate this self-imposed isolation and allow reengagement in favorite activities. The adolescent often felt lonely and unloved, and this feeling was associated with self-deprecatory ideation and a poor self-image. Inability to concentrate and social withdrawal were reflected in diminished school performance. Suicidal ideation and acts and running away from home could be seen as attempts to deal with all of the chronic problems. Insomnia, defined as delayed sleep or early waking, and tiredness upon awakening were frequently present.

It is important to note that loss of interest, apathy, boredom, loss of pleasure, poor concentration, diminished school performance, and suicidal ideation were present in over 70% of the sample, whereas memory disturbance, irritability, loss of appetite-weight loss, subjective anergia, thought slowing, diminished libido, and somatic symptoms were present in less than 40%.

DISCUSSION

Depression in adolescence has been considered similar to that in adulthood, but the type of adult depression on which the comparison is based has often been unclear. The classification of affective disorders in adults is itself considered to be in disarray (14). Our study suggests that although there are many similarities between the features of adolescent and adult depression there are also many differences, at least in early and mid-adolescence, which warrant more cautious comparison and further study. Thus, our study is not in agreement with Hudgens' conclusion that adults and adolescents are similar with respect to the clinical picture of depression.

"Masked depression" and "depressive equivalents" have not been defined precisely enough to allow comparison, but symptoms that are associated with these diagnostic terms, such as irritability, aggressive behavior, antisocial activity, and promiscuity, were infrequent in the present study. The lack of clarity in the initial clinical picture, including the absence of "observed depression" (i.e., the patients looked sad or cried transiently during the interviews) may have contributed to the origin of the terms "masked depression" and "depressive equivalents." Although the adolescents in this study did not initially look sad, they were found on systematic inquiry to have a broad psychopathological symptom profile, along with the more easily identifiable behavioral components. This initial clinical picture may also be the basis for clinicians' underrecognition of depression in adolescents.

It has been suggested that "prevailing attitudes in Child Psychiatry . . . fail to stress a systematic clinical approach to diagnosis" (15). This is also the case in

olescents: "Myths alluding to the tumultuous nature adolescence and the benign affects of adolescent mptom formation continue to abound" (16), and di-nostic criteria are not adequately defined. The study defined symptoms associated with depressed moods ring adolescence is an approach that could help es-olish diagnostic criteria in follow-up studies for a m, or forms, of depression during adolescence. Pos-le future prospective and retrospective studies uld link child, adolescent, and adult depressive phe-mena and define the "underlying invariant nature" the disorder. We are planning a follow-up study that ll attempt to define diagnostic criteria and to deter-ne the clinical course and natural history of the af-ctive disorder in this sample.

Special Issue of *AJP* to Feature Depression and Alcoholism

A special issue of the *American Journal of Psychiatry* will be published in mid-April 1979. This issue, which will be distributed to all subscribers and is in addition to the regular April issue, will consist of a collection of articles on the subjects of alcoholism, depression, or both. Articles will deal with such topics as the treatment of depression with imipramine and ECT; bipolar illness: factors in drinking behavior; physical activity and plasma cyclic AMP in manic-depressive patients; childhood depression; life events at the onset of bipolar affective illness; psychiatric problems in women at alcoholic detoxification; lithium maintenance; efficacy of drugs, and psychotherapy in the treatment of acute depressive episodes; and life events, coping, stress, and depressive symptomatology.

Authors include David Avery, M.D., Jesse O. Cavenar, Jr., M.D., David L. Dunner, M.D., Ronald R. Fieve, M.D., Eric W. Fine, M.D., Evelyn L. Goldberg, Sc.D., John Hamm, M.D., Shirley Hill, Ph.D., Eleftherios Lykouras, M.D., Anthony Marsella, Ph.D., Roy Mathew, M.D., Jerome Motto, M.D., Irving Philips, M.D., Timothy Rivinus, M.D., Fred Steinberg, Ph.D., Marc Schuckit, M.D., Robert Belmaker, M.D., Martin Keeler, M.D., Paul Garfinkel, M.D., John Helzer, M.D., James Kocsis, M.D., Myrna Weissman, Ph.D., Alberto DiMascio, Ph.D., Gerald Klerman, M.D., Larry Ereshefsky, Pharm.D., Michael R. O'Leary, Ph.D., Steven J. Wolin, M.D., George J. Warheit, Ph.D., and Walter A. Brown, M.D.

Extra copies of the special issue will be available from the APA Circulation Department at a cost of $2.25 for domestic orders and $2.90 for foreign orders.

Mental Health Services for Medicaid Enrollees in a Prepaid Group Practice Plan

BY SIDNEY S. GOLDENSOHN, M.D., AND RAYMOND FINK, PH.D.

The authors present the patterns of utilization of mental health services of a low-income population in a prepaid group practice setting, the Health Insurance Plan of Greater New York (HIP). Over a 6-year period, utilization rates for psychiatric consultations and mental health services by Medicaid enrollees rose to equal or exceed utilization by employed groups. The authors also provide evidence that psychiatric treatment reduces the use of other physician services, especially X-ray and laboratory services.

IN THESE TIMES of growing welfare expenditures and spiraling health care costs, the method of delivery of mental health care to low-income persons has become increasingly important. For more than a decade Medicaid programs have provided financial support for health care services for the poor. During that time modalities of treatment, costs, and effectiveness of services have been studied.

We will describe patterns of utilization of the mental health care provided in a prepaid group practice setting to low-income (Medicaid) enrollees and compare these patterns with those of employed groups. The characteristics of the therapeutic program as they affect accessibility and utilization will be noted. We will also present data from a study conducted for the National Institute of Mental Health on the effect that use of mental health services has had on this low-income population's utilization of nonpsychiatric health services.

This study is based on information derived from about 16,000 Medicaid enrollees from six medical groups in the borough of Queens that are affiliated with the Health Insurance Plan of Greater New York (HIP), a prepaid medical group practice. When mental health treatment was indicated, these enrollees were referred to the Mental Health Service of HIP's Queens-Nassau Center, which has been described elsewhere (1, 2). brief, mental health services are available to HIP su scribers on the basis of a rider to the prepaid heal insurance plan. Approximately 180,000 enrolle bought the psychiatric rider. New York City acquir the rider coverage for about 48,000 of its welfare reci ients. The 1978 annual premium was $9.48 per persc There are no deductibles or copayments, and, course, no premium costs to Medicaid enrollees. broad spectrum of mental health services is offere The basic therapeutic orientation is psychodynam although this orientation may be significantly modifi for low-income enrollees. The goal of treatment is return the patient to a functioning level as quickly possible. Usual in-hospital treatment modalities a provided. Psychotropic drugs, both in and out of t hospital, are supplied to the patient without additior cost.

UTILIZATION OF MENTAL HEALTH SERVICES

In 1970, the second full year in which mental hea services were provided to Medicaid enrollees, servi utilization rates were lower for Medicaid enrolle than for the other two major contractor groups who members are under 65 years of age—federal emplc ees and their families and New York State employe and their families. Since 1970, however, service uti zation rates of Medicaid enrollees have increased, a in 1976 they exceeded the rates of the federal a New York State employees. Rates were 271 servic per 1,000 Medicaid enrollees; 223 per 1,000 federal e rollees; and 199 per 1,000 New York State enrollee

These changes in Medicaid enrollees' utilizati rates reflect increases in both the rate of those enteri the treatment system through initial consultation a the average number of services per treated patient. 1970, the consultation rate was below that of both fe eral and state employees and their families, but it h also increased to rates similar to those of the fede group and in excess of those in the state group (s table 1).

The increases in utilization took place during a pe od of declining Medicaid enrollment. Concurrentl the number of services to HIP Medicaid enrollees l nonpsychiatric physicians also increased. During t period from 1970 to 1976, Medicaid enrollees' avera annual utilization of nonpsychiatric physician servic

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received March 8, 1978; revised Aug. 17, 1978; accepted Sept. 20, 1978.

Dr. Goldensohn is Director, Mental Health Service, Health Insurance Plan of Greater New York, 625 Madison Ave., New York, N.Y. 10022. Dr. Fink is Professor of Community and Preventive Medicine, New York Medical College.

cludes about 1% in each year 65 years of age or older not covered by Medicare.

)r those under 65 years of age) increased from 149 r 100 enrollees to 361 per 100. In 1970 the ratio of edicaid enrollees' services to non-Medicaid (under years of age) enrollees' services was .60, increasing .85 in 1976. In contrast, as observed above, Medi- id utilization of mental health services in 1976 ex- eded that of non-Medicaid persons eligible for these rvices.

These findings are of particular interest when one nsiders the characteristics of the Medicaid popu- :ion. Medicaid enrollees tend to be less educated an the other subscriber groups; studies (3, 4) have own that those with little education tend to be lower ilizers of mental health services.

It is commonly believed that the low-income person so has a greater tendency to drop out of treatment rly. Our utilization picture, however, is more com- ex. Among those who start treatment, Medicaid pa- nts are more likely than others to end therapy before e sixth visit. Data compiled during the 3-year period om January 1972 through December 1974 show that eatment ended before the sixth visit for 53% of the edicaid enrollees, 43% of federal enrollees, and 35% state enrollees. These data are reported in greater tail elsewhere (5). However, of patients who stay in erapy until the sixth visit, Medicaid patients attend ore sessions than the other groups: the average num- r of sessions per patient per year in 1976 was 18.4 for edicaid patients and 15.4 for employee groups.

'ECIAL CONSIDERATIONS THAT FFECT UTILIZATION BY LOW-INCOME AMILIES

The ability to establish therapist-patient rapport is a quirement for any program aimed at reaching those need of mental health care. Among low-income fam- es, a population that is generally less likely to use alth services, special approaches are required to hieve this goal. For all patients, low income and oth- s, the accessibility of mental health services is clear- essential. In the Queens-Nassau Center easy access attained through unrestricted self-referrals and also rough family physician referrals. Financial consid- ations do not enter the decision to seek therapy; edicaid patients are reimbursed for carfare to the nter. Further, staff are available for urgent or walk- in appointments. Required psychotropic medications are provided at the center, so that needed drugs are obtained without delay.

Once a patient is in contact with the Mental Health Service, the ambience provides further incentive to use the program. The physical setting has little resemblance to the clinic atmosphere so often associated with health care in organized settings. Receptionists are friendly and welcoming. Comfort and understanding are increased by an interracial and bilingual (Spanish) professional staff, since Spanish is the first language of much of our Medicaid population.

Therapeutic orientation is strongly influenced by community mental health principles (6) and techniques. There is emphasis on promotion of functional competence rather than self-actualization and an adherence to a multidetermined view of etiology—psychological, social, biologic, genetic, and educational. Intervention takes place as much as possible within the real-life settings of family, friends, work, school, and community. There is much therapeutic reliance on natural helpers such as spouse, parents, siblings, and peers, and a three-step therapeutic technique of advocacy-mediation (7) is used for and welcomed by many of the underprivileged patients, particularly those who have never been financially self-sufficient.

The Medicaid population can be divided into those who have never been financially self-sufficient and those who have. The latter group are better able to respond to the more usual psychodynamic modalities. In contrast, the former group, often generational welfare families, respond best to concrete help and advocacy-mediation techniques. Since there is overlap, flexibility is required, and we have learned that the traditional therapeutic relationship may still be the treatment of choice for individuals at any socioeconomic level.

EFFECT OF MENTAL HEALTH SERVICE ON UTILIZATION OF OTHER HEALTH CARE SERVICES

The desirability of integrating mental health care and medical care is generally accepted. The benefit of ease of referral has already been noted. Another benefit is the facilitation of close communication between the physician and psychotherapist; the psychiatrist has

for too long been isolated from the primary care physician. Still another benefit—that there will be a reduction in use of nonpsychiatric health services as a result of the use of mental health services—is not as well proved, although the issue has been systematically examined on several occasions. In 1967 Follette and Cummings (8) reported on changes in medical utilization among samples of Kaiser Plan enrollees matched for age, sex, and emotional impairment; one sample (the treated group) had received mental health care from the Kaiser Plan, the other had not. Over a 3-year period following mental health care, the treated group was found to have had fewer health care services (including hospitalization) than the untreated group. In 1968 the Health Insurance Plan of Greater New York (HIP) (9) compared changes in utilization over a 2-year period and observed a tendency toward a reduction in the use of other health services by a group which had received mental health care. In 1969 Group Health Association of Washington, D.C. (10) observed a drop in the use of non-mental health services among patients who had used mental health services. None of these studies was able to obtain a control group of untreated persons who had sought psychotherapy. Nevertheless, there is a widespread impression that mental health services do contribute to a reduction in utilization of other health services.

In 1972, a special study was conducted among a random sample of HIP Medicaid enrollees treated in the Queens-Nassau Mental Health Center to examine the relationship between mental health treatment and utilization of other health services. Like the studies just cited, this study could not generate a randomized control group of patients who had sought psychotherapy and did not receive any; therefore the same reservations in interpretation pertain to this report as to the others.

The Samples

Two random samples of Medicaid enrollees were selected. One, designated as the treatment group, consisted of 263 persons who received one or more mental health services at the Queens-Nassau Mental Health Service of HIP in 1969 or 1970. The second, consisting of 206 persons and designated as the diagnosis group, was a random sample from the same HIP medical groups in Queens for whom an HIP physician indicated on a routine reporting form in 1970 a condition classifiable under the International Classification of Diseases as a mental, emotional, or psychological condition. Nearly all of these were diagnosed by family physicians; none was treated at the Mental Health Service. Medical records covering a 2-year period were reviewed for both groups. For the treatment group, services were counted for a full year preceding the first psychiatric consultation that led to treatment and the full year subsequent to onset of treatment. For the diagnosis sample, services were counted for the full year preceding the date of the diagnosis and the year following the diagnosis. (The physician visit in which the diagnosis was given was not included in the count of services.)

TABLE 2
Sex and Age of Medicaid Diagnosis and Treatment Samples

Variable	Diagnosis Sample (N=141) N	%	Treatment Sample (N=1 N
Sex			
Male	27	19	68
Female	114	81	101
Age			
Under 25	27	19	88
25–44	35	25	51
45 and over	79	56	30

Since the review was limited to those persons f whom information was available for the full 2-year o servation period, the treatment group was reduced 169 persons (64% of the original sample) and the dia nosis group reduced to 141 persons (68% of the ori nal sample). Age and sex characteristics of ea sample were tabulated,

Substantial demographic differences were found the age and sex breakdown between the treatment a diagnosis samples; the treatment group had ma more males and was younger than the diagnosis gro (see table 2). This skew is due to the large number young males with school behavior problems: ma boys with behavioral disorders bypass their fam physicians and are referred directly to the Men Health Service by their schools. The 25–44 year a group provides the sharpest picture of the differenc between the psychiatrically treated and untreat groups, with 56% of the diagnosis group and 18% the treatment group in this category.

Differential Utilization of Services

The two groups were compared on their use of fa ily physicians, specialists, and X-ray and laborato services. In addition to presenting the average numb of services for each group, we also calculated the n change between the year before and the year after, a the net difference between the treatment and diagnos groups. A negative measure indicates a change in t direction of fewer services for the treatment group.

Effect on family doctor services. In comparing fa ily physician utilization, there was a modest drop f the treatment group and a slight rise for the diagnos group. For the treatment group, the average number family physician services in the year before treatme was 3.8 and for the year after the start of treatment was 3.4 services, a drop of 0.4 services. In contra the diagnosis group had an increase of 0.2 services f the year following physician diagnosis. The net d ference for the total sample comparisons, therefore, −.6, indicating a relative decline in family physici services for the treatment group (see table 3). Age a sex differences are also provided; especially notewo

was the net difference of −2.1 for the 25–44 year group and − 1.3 for women (see table 3), in both es declines in the direction of reduced utilization the treatment sample.

ffect on specialist services. The treatment sample a decrease of .3 specialist services between the ar before and the year after the start of treatment the diagnosis group had an increase of .3 specialist vices; the net difference was therefore a decrease of 5 specialist services. The net difference for the men's treatment group was −1.0, and for the 25–44 r age treatment group −1.2 (see table 4), more evi- ce of reduced utilization of non-mental health serv- s following psychiatric treatment.

ffect on X-ray and laboratory tests. By review of dical records, we were able to count each X-ray and oratory test procedure; each procedure was nted as a service. The net difference between the groups, −5.0 services, was surprisingly large (see le 5).

The marked reduction in X-ray and laboratory services following psychotherapy contrasts with a more modest reduction in other medical services. One possible reason may be that some primary physicians are uncomfortable and frustrated when they are medically responsible for an intensely nervous patient who is not under psychiatric care; as a result, these physicians may tend to temporarily "dismiss" this patient with a referral for an X-ray or laboratory procedure. Another speculative explanation for the large differences in X-ray and laboratory utilization by the two groups may be that the psychiatrically untreated sample had a higher incidence of psychosomatic or conversion symptoms than did the treated sample. Still another possibility is that psychotherapy brings about a reduction in somatic symptomatology. Unfortunately, we do not have the kind of data that could test these hypotheses. Future research that looked at the physical diagnoses of both samples under study could be fruitful; it might identify the kinds of conditions that show the greatest reduction in medical services as a result of mental health care.

DISCUSSION

During the period from 1970 through 1976, utilization rates for new psychiatric consultations and mental health services by Medicaid enrollees rose to equal or exceed utilization by employed groups. This was true in spite of the higher early dropout rate of the Medicaid enrollees.

Comparisons between utilization rates of non-mental health services by Medicaid enrollees treated in the Mental Health Center and Medicaid enrollees diagnosed as having emotional problems but not treated provided evidence that psychiatric treatment reduces the use of other physician services and especially of X-ray and laboratory services. Although these findings are not consistent in every age and sex comparison, they occur with sufficient regularity to support the hypothesis of reduced medical utilization for those receiving treatment for emotional conditions. Thus, while the poor require as many or more mental health services as do middle-income groups, the cost for these services may be somewhat reduced by lower utilization of other services following psychotherapy.

In a household survey among samples of Medicaid enrollees treated at the Mental Health Center and those diagnosed but not treated at the center, 17% of the treated group indicated they had also sought care in other settings, while among the diagnosed but untreated group 11% had sought mental health treatment outside of HIP. Among those who were treated at HIP, satisfaction with the care was high: three out of four said they would seek treatment again in the HIP Center, and two-thirds reported the treatment as being either very or fairly helpful.

We now have 10 years of experience in providing mental health care to the Medicaid population in a prepaid medical group practice setting. On the whole, we believe that this is a feasible method of delivering mental health care to a low-income group. While there are variations in their utilization patterns, over a period of time the differences appear to be minor and ca dealt with appropriately. Innovative therapeutic n agement of the low-income multiproblem family mains a continuing challenge in any delivery syst but treatment in a setting that also includes blue-c and middle-income patients may be a therapeutic p A problem of some magnitude that remains is the stantial attrition rate of Medicaid enrollees from medical plan itself. It is necessary that we deter the causes of the attrition and reverse the trend.

ne "Moonies": A Psychological Study of Conversion and embership in a Contemporary Religious Sect

MARC GALANTER, M.D., RICHARD RABKIN, M.D., JUDITH RABKIN, PH.D.,
O ALEXANDER DEUTSCH, M.D.

authors undertook this study to enhance chiatric understanding of contemporary rismatic religious sects. After a pilot study, a resentative sample of members of the Unification rch (N = 237) completed a 216-item structured stionnaire. Respondents were below the mean for ıge- and sex-matched group on a psychological eral well-being scale, and they reported ificantly greater neurotic distress before version. The authors discuss correlates of an roved emotional state following conversion and loy attribution theory, drawn from social chology, to put the conversion process into a chiatric perspective.

S STUDY was undertaken to investigate the psychocal state of members of a charismatic religious cult ı regard to the nature of their conversion and coned membership. In recent years there has been cern about the techniques used to effect consions and retain members in certain contemporary gious cults. This has presented a challenge to psyıtry as a discipline, since psychiatrists are frequentalled upon to deal with these matters in both theratic and legal settings. However, psychiatrists are n confronted by issues not readily subsumed under r usual diagnostic and phenomenologic approach. order to shed light on these issues, we elected to roach the Unification Church since this group has n the focus of much concern regarding its effect on verts. The church cooperated because of an exssed interest on the part of its administrative leadıip to demystify the organization in the eyes of the lic by means of an impartial, professional study.

he Unification Church was introduced into the ited States by Korean missionaries in 1961. There are chapters throughout this country, as well as allied branches in Korea, Japan, and western Europe. Members of the church have been referred to as "Moonies" because they are followers of the religious leader Reverend Sun Myung Moon. Their considerable efforts at serving their church have focused attention on the depth of members' commitment. In addition, the efforts of family members to "deprogram" this commitment have raised both legal and psychiatric questions regarding the appropriateness of such undertakings.

METHOD

The project was carried out over a period of 6 months, during which we initially conducted psychiatric interviews and psychological testing of 20 church members to clarify individuals' relationship to the movement.

Questionnaire

On the basis of this and previous work by one of us (1), a 216-item computer-codeable questionnaire was composed and refined by pretesting on church members. Three scales were included in the questionnaire, each composed of a series of items.

1. *Neurotic Distress Scale.* This 8-item scale was used previously for retrospective assessments in relation to stages of membership in a religious sect (1). A score of 1–5 (not at all, slightly, moderately, a lot, and very much) is given to each of a series of statements that reflect neurotic symptoms. Sample items from this scale include, "I felt nervous and tense," "I felt depressed and glum," and "I had trouble controlling my thoughts." Respondents were to choose an answer for each item for each of 4 periods: 1) the most symptomatic period before contact with the church, 2) right before first contact with the church, 3) right after conversion, and 4) the last 2 months.

2. *Religiosity Scale.* This 9-item scale was devised to reflect the intensity of religious commitment to the church. Items dealt with the following: feeling "a close connection to God"; gaining meaning from prayer and meditation; feeling that others "should adopt the same religious beliefs that I do"; and avoiding "thinking about sex" or "getting high from alcohol." Responses were solicited for attitudes for periods 2–4 on the Neu-

ented at the 131st annual meeting of the American Psychiatric ociation, Atlanta, Ga., May 8–12, 1978. Received April 3, 1978; ed June 26, 1978; accepted Aug. 11, 1978.

rotic Distress Scale. The choices of answers were those used for the Neurotic Distress Scale.

3. *General Well-Being Schedule*. This 18-item scale was developed to measure psychosocial adjustment in a self-administered assessment of health status (2). Scaled responses to items addressed issues such as, "How have you been feeling in general?" "Have you been feeling emotionally stable and sure of yourself?" and "How happy, satisfied, or pleased have you been with your personal life?" A comparison group was drawn from a study of 1,196 representative adults from Dayton, Ohio (3), with the collaboration of Dr. John Ware. The comparison group (N=305) was balanced with the respondent group for age and sex. The degree of well-being in this schedule is construed as proportional to the reported scale scores. The Neurotic Distress Scale score for the last two-month period and the General Well-Being Schedule score for the last month had a high inverse correlation in this study population ($r=-.64$, $p<.001$).

The questionnaires were administered under our direct supervision to a representative sample of full-time members who lived in the church's residences in a large metropolitan area. Standardized instructions were used in all settings. Respondents were also instructed by senior church figures to give frank answers to the anonymous questionnaire. Because it was an officially sanctioned church activity, full cooperation was elicited. A total of 237 questionnaires completed by native-born Americans were used for data analysis; these were from a total sample that included an additional 70 questionnaires from non-Americans. Because of the mobility of church members in the United States, this sample included members from all regions of the country.

FINDINGS

Respondents' Backgrounds

Most of the members were unmarried (91%), white (89%), and young (mean age=24.7 years). Male members predominated (61%); this is true for the membership of the church nationwide (62%) as reflected in church records. Two-thirds (69%) had been members over 18 months, and the mean duration of membership was almost 3 years (33.5 months). Most (67%) regarded themselves as at least moderately committed to their family's religion before the age of 15. At some point thereafter, one-third (34%) became at least moderately committed to one of the Eastern religious sects, such as the Divine Light Mission, Zen, and Muktananda, and a smaller proportion (19%) to fundamentalist Christian sects. However, fully 90% reported a history of at least some prior commitment to these sects. This figure may be compared with the much smaller proportion (47%) who indicated at least some past commitment to a political party or movement.

Almost half (42%) had attended school on at least a half-time basis during the 6 months before joining the church. Upon joining, however, members tende leave school; only 25% of the members completed lege, although more than half (58%) had begun. dropping-out process began before entering church, since less than one-third (31%) of the resp ents who were students during the 6 months be conversion were actually enrolled full-time.

TABLE 1
Mental Health Scale Scores

Item*	Score Mean	SD	t
Neurotic Distress Scale (study group, N=237)			
Most symptomatic period before contact with church	20.5	6.8	
Right before first contact	18.0	6.0	17.73
Right after conversion	12.6	3.7	1.5
Last 2 months	12.2	3.3	
General Well-Being Schedule			
Study group (N=237)	74.4	17.2	6.24
Comparison group (N=305)	83.4	16.2	

*A product moment correlation was done for the mean scores of the group on the Neurotic Distress Scale (last two months) and the G Well-Being Schedule ($= -.64$, $p<.001$).

Members experienced a fair amount of psychol cal difficulty before joining the church. A sizable tion (39%) felt that they had had serious emoti problems in the past. This had led many to profess al help (30%) and even hospitalization (6%). Thei sponses yielded neurotic distress scores that were nificantly higher before joining than at the time of study (table 1). Even though they reported a declin neurotic distress over the course of membership, t current emotional well-being, reflected in the Gen Well-Being Schedule, was lower than that for matched comparison group. In addition, their prior of drugs was high. One-quarter (23%) said that t had had serious drug problems in the past, and the p tion who had ever used drugs of abuse was higher t for a comparable national sample (for example, us hallucinogens was 45% versus 14%) (4).

Conversion

Conversion usually occurred during a series church-run workshops. For those who volunteere remain, a typical sequence might be a 1-day works followed immediately by a 2-day workshop and th 7-day workshop. The workshop day runs from 8 a.m. to 11:00 p.m. and includes lectures and group cussions related to religious issues, as well as sp and entertainment that are sometimes related to r gious themes. Virtually the entire day, incluc meals, is spent in the immediate company of works and church members. Initially, participants are o not aware that the workshop is associated with church. However, in our interviews members repo no overt coercion or physical deprivation during period. In fact, when they were asked to indicate strongest action taken at any point to discourage th

m leaving the church, 97% indicated that there was more than some disapproval or a little argument. owever, 2 respondents (1%) did report members vertly limiting [their] freedom of movement or trav- but for less than an hour."

The large majority of respondents (91%) gave re- onses that yielded lower neurotic distress scores for e period right after conversion than for the period ht before, with a mean decline of 30%. This is com- rable to a decrease from "moderately" (score 3) to lightly" (score 2) for typical items, such as "I felt pressed and glum." Religiosity was associated with greater decline in symptoms. For example, if sub- ts are ranked according to the degree of improve- nt in distress, the quartile who improved most owed a 128% increase in their reported religiosity ores over the course of conversion, while those who proved least showed a 76% increase (one-tailed t st, t=3.67, p<.01).

Most of the respondents recalled the conversion pe- d in a positive way. A large portion reported having e following feelings "a lot" or "very much" more an usual: "a great deal of respect for another per- n" (67%), "cheered up" (43%), "close or intimate th other people" (48%), and "an appreciation of the ality of God" (76%). For some, however, the experi- ce entailed psychologically disruptive components. me respondents reported having the following expe- nces "a lot" or "very much" more than usual: onflict or unhappiness" (19%), disruption of eating 2%) and sleeping (21%) habits, and feeling they were nder someone else's influence" (12%).

Transcendent experiences were not uncommon dur- g the conversion period, with many respondents re- rting that they experienced the following either retty clearly" or "very intensely": "a special unfa- iliar feeling in my body" (45%), "the presence of meone important to me, even though most people uldn't have seen him" (35%), and "time passing ower or faster than usual in a very special way" 9%). Not uncommon was the type of experience de- ribed by one member who had no prior or sub- quent history of psychiatric disturbance. After a pe- od of prayer at home following a workshop, he saw e face of the Reverend Mr. Moon in front of him and ard him speaking directly, revealing his mission, "as al as we're talking now."

ntinued Membership

"Full-time" membership in the church entails a ma- r life commitment. For example, in the 2 months be- re the survey our respondents, who were full-time embers, spent almost all (mean = 94%) of their nights a Unification Church residence. Commitment to reli- ous principles was also very high; regarding belief, r example, three-quarters (74%) felt a "close con- ction with God" "a lot" or "very much." Specific ohibitions were closely adhered to, and 76% felt that ey should avoid thinking about sex "very much," as posed to only the small minority (11%) who felt this way before joining the church. A large majority of respondents (90%) indicated that they had "pretty clearly" or "very intensely" "seen a special new meaning in life" during daily prayer. There was, in fact, a significant correlation between current scores on the religiosity scale and scores on the General Well-Being Schedule (r=.34, p<.001).

Members' commitment was also reflected in the number of hours worked per week at a regular job, charitable work, or course work. They reported an average of 67 hours, compared with 41 before joining. Street proselytizing and sales was the principal job activity for the majority (52%) of members. This zeal was reflected in most members' strong feeling that people who were not members of the church should "adopt the same religious beliefs that I do" (80%) and "avoid thinking about sex," as they did (86%). It should be noted that the number of hours of work was not significantly correlated with sex, age, duration of membership in the church, or score on the religiosity scale. It was, in fact, positively correlated with the general well-being scores (r=.19, p<.05).

However, the general well-being scores were significantly below the mean for the age- and sex-matched comparison group. As indicated in table 1, there was no significant net change in the mean neurotic distress score from the time right after conversion until the time of the questionnaire, but there was considerable variation in change among individual members (mean change=3.2%±26.3%).

In order to examine this variability, items associated with an increase in the neurotic distress score after conversion were ascertained in two stepwise multiple regression analyses. The two criterion (dependent) variables were 1) the relative increase in the reported neurotic distress score from the 2-month period right after conversion up to the time of questionnaire administration (first analysis), and 2) the actual neurotic distress score for the current 2-month period (second analysis).

The variables tested as predictors (independent variables) were drawn from items related to personal background, prior neurotic distress scores and changes in score, and experiences during conversion. These independent variables were entered into the regression equation as long as they accounted for a sufficient portion of the variance to be significant at the .01 level. The 10 best predictors in each of the regression analyses are listed in table 2 in the order in which they were entered. A subject's increases or decreases in neurotic distress scores were defined relative to the mean change for all members; for example, an increase of 10% in the score was considered as a relative decline if the mean change for all subjects was an increase of 25%.

The first analysis (table 2) provided information on the relative importance of demographic and experiential variables in accounting for variance in the amount of change in neurotic distress scores after the conversion period. Variables associated with an in-

TABLE 2
Results of Stepwise Multiple Regression Analyses

Item	Time Period	R	R^2	Simple r	Beta Weig
First analysis: predictors of an increase in neurotic distress score after conversion period					
Decline in work satisfaction	After the conversion period	.31	.09	.31	.1
Decline in theistic belief	After the conversion period	.37	.13	.30	.3

Relative decrease in theistic belief	Over the course of conversion	.69	.48	.00	.2

*Versus male gender.

crease included a decline in theistic belief and work satisfaction after conversion, along with less religious commitment before conversion. In addition, subjects reporting a higher neurotic distress score before conversion and a relative increase in neurotic distress score over the course of conversion were more likely to experience an increase in the neurotic distress score during subsequent membership.

A higher score at the time of the questionnaire was associated with the following constellation: less religious commitment right before joining and a decrease in theistic belief over the course of membership (table 2). However, one-third of the variance in the current neurotic distress score was accounted for by a high score before conversion and a relative increase in the score over the course of conversion.

DISCUSSION

In studying such a sect, questions may be raised as to the reliability of survey responses. Objective information on current circumstances can probably be taken at face value, given the instructions for frankness from both the church organization and the research team, although subjective reports, particularly retrospective ones, may be vulnerable to unintended distortion (5). It should be noted, however, that self-assessments of mental state on the General Well-Bei Schedule were not higher than those for the co parison group, even though enthusiasm might have l to an overstatement of good feelings. Findings are, a plicable only to converts who retained membersh since those who had dropped out would most lik have presented some critical differences in their sponses. With these points in mind, the following sues bear emphasis.

The average convert apparently experienced en tional distress before joining. The scores reported the Neurotic Distress Scale for the period before c version were considerably higher than those for period after conversion, or for the present. In additi current scores reflected somewhat greater distr than those of a like-aged comparison group. The lik hood of a higher incidence of psychiatric illness in t population is indicated by the high percentage of th who had sought prior professional help and hospit ization for emotional problems.

Affiliation with the Unification Church apparen provided considerable and sustained relief from n rotic distress. Although improvement was ubiquito a greater religious commitment was reported by th who indicated the most improvement. Similar i provements have been reported for affiliation amc members of Eastern religious cults (1, 3) and those Erhard Seminars Training, a hortatory self-impro

ent group (6). In addition, the anxiety-reducing as-
cts of religious experience have also been noted to
ay a role as a suicide preventive (7).

Continued membership also appeared to support a
rtain stability in psychological status, as seen in the
milarity between the mean scores for neurotic dis-
ess both right after conversion and at the time of the
rvey. After an average of almost 3 years, most sub-
cts still reported a diminished level of distress. How-
ver, an increase in distress over the course of mem-
rship was reported by some subjects, such as those
ho reported a decline in work satisfaction and reli-
ous commitment over the course of membership.
lembers who reported greater improvement in neu-
tic distress over the course of conversion tended to
turn to their previous levels of distress over the
urse of membership.

The nature of religious conversion may be discussed
ith recourse to the findings presented. Lifton has dis-
ssed noncoercive "personal change," in contrast to
thought reform [brainwashing]" (8). He quoted Wil-
am James, saying that "conversion is in its essence a
rmal adolescent phenomenon, incidental to the pas-
ge from the child's small universe to the wider in-
llectual and spiritual life of maturity" (8, p. 469). It
ay be noted that many of our respondents were in-
ed in such "passage" prior to joining. This was re-
cted in their generally premature movement away
om the school setting and their interest in Eastern
d fundamentalist religious groups. In addition to this
ansition in commitment, many were apparently ex-
riencing considerable emotional distress, leaving
em open to an alternative perspective that would
ovide relief.

The issue of brainwashing has been raised regarding
ntemporary cults. In discussing brainwashing and
ought reform, Lifton described changes in world-
iew forceably effected in military captives. This
rves to highlight some similarities to as well as dif-
rences from the conversion context described here.
elevant to both situations is the importance of some
ntrol over the milieu of communication. The Unifi-
ation Church workshops entail a series of carefully
ructured experiences that give increasingly more ex-
licit messages for commitment. On the other hand,
ose present at the workshops had voluntarily pre-
nted themselves. They were more likely to be open
a new perspective than the brainwashed, physically
erced subjects who were unwilling captives at the
itset. The brainwashed captives described by Lifton
ere typically abused and coerced into compliance,
mething not reported by our subjects.

Attribution theory (9) presents a model for decision
aking that is drawn from social psychology and
osely related to the theory of cognitive dissonance
). It points to the tendency of individuals to uncon-
iously seek "plausible explanations for their feel-
gs among whatever explanations are available in an
vironment" (10, p. 323), that is, to attribute causa-
on based on the available cognitive input. Attribution theory has recently been applied to the study of religious conversion. Its operation may be observed when there is a disequilibration of a person's subjective state, such as was recalled regarding the conversion period by respondents in relation to their feelings and their perceived interpersonal milieu. With the cognitive input during this period determined by the church members directing the workshop, the participants may be implicitly encouraged to attribute their altered experience to a new explanatory set. The potential relief of neurotic distress experienced over the course of religious affiliation may indeed play an implicit role in this process.

This description serves to highlight some aspects of cognition, affect, and communication in relation to conversion. The converts' needs for social affiliation would certainly influence responses to a setting where conversion may occur. We have dealt with this latter issue elsewhere at greater length, using data from another sect (11).

Conversion might be compared to the crystallizing role of the experience of significance sometimes found at the onset of delusion formation, in the face of emotional disruption on a much more severe and pathological level. Indeed, most respondents (71%) did recall that there was one point at which their conviction to join coalesced. However, a salient difference is the autistic origin of the experience of significance, as compared with attribution during the conversion experience, which is consensually validated within the context of the religious group.

After the initial conversion, life experiences and activities gain meaning within the elaborated beliefs of the attribution set. For example, it has been pointed out that for American faith-healing subjects, within their "assumptive world view" their personality structure and magical beliefs are not abnormal, but rather are part of a coping system that provides ego integration (12). Reflections of this are seen in the positive relationship between the respondents' diminished state of distress and the intensity of their religious commitment, as well as their willingness to increase work hours, with greater work hours correlated with greater emotional well-being.

Foundations' Fund Fellowships for Sabbatical Research in Psychiatry and Its Basic Sciences

The Foundations' Fund for Research in Psychiatry announces a limited program of support for scholars on sabbatical leave in order to further their research and contribute to the knowledge of psychiatric diagnosis, treatment, and prevention. The sabbatical must be spent away from the home institution at an internationally recognized institution.

Applications are open to distinguished and creative investigators with demonstrated research contributions in the field who hold full-time positions in professional schools and graduate departments of universities or equivalent institutes of research. Applicants must be U.S. or Canadian citizens or permanent residents of the U.S. or Canada.

The deadline for receipt of applications is May 1 of the year preceding the proposed sabbatical.

Effects of Interpreters on the Evaluation of Psychopathology in Non-English-Speaking Patients

Y LUIS R. MARCOS, M.D., MED.SC.D.

Non-English-speaking patients in need of psychiatric services are usually evaluated with the help of an interpreter. Discussions with psychiatrists and lay hospital interpreters who had experience in these interviews and content analysis of eight audiotaped interpreter-mediated psychiatric interviews suggested that clinically relevant interpreter-related distortions could lead to misevaluation of the patient's mental status. The author notes that pre- and post-interview meetings of clinicians and interpreters have been found useful in minimizing these distortions.

N NEW YORK CITY, patients whose primary language is not English constitute a significant proportion of the psychiatric population. A number of these patients speak enough English to allow some communication in this language. The problems involved in the psychiatric evaluation and treatment of this bilingual population have been the subject of recent experimental and clinical studies (1–5). However, many patients' competence in the English language is so low that communication can be established only with the help of an interpreter.

At Gouverneur Hospital and Bellevue Psychiatric Hospital, two New York City institutions affiliated with New York University, an average of 30 psychiatric interpreter-interview evaluations are conducted daily. In both hospitals the two most commonly spoken languages apart from English are Spanish and Chinese (i.e., Cantonese and Toisonese). Neither hospital has official interpreters (to my knowledge this is true of all psychiatric institutions) so any available individual who can speak the patient's language may be asked to interpret in evaluations of the non-English-speaking patient. The interpreter may be another patient, a patient's friend or relative, or a member of the hospital staff.

To my knowledge, the effect of the interpreter-mediated interview on the assessment of psychopathology has not been studied systematically, and an exhaustive literature review revealed only a brief description of the interview's process (6) and one clinical report (7). In that report, Sabin reviewed two cases of suicide by Spanish-speaking patients who were evaluated and treated by English-speaking psychiatrists with the aid of an interpreter. Because the evaluating clinicians had made the same clinical error independently of one another, Sabin ruled out clinician effect as an explanation for the outcome and concluded that the patients' emotional suffering and despair may have been selectively underestimated in the process of interpretation. His report was a retrospective study based on a review of the patients' psychiatric records, so it is difficult to evaluate the extent to which the clinicians' written reports contributed to their conclusions.

A review of the general literature on interpretation and translation did not offer any particular information applicable to the special practice of psychiatric interviewing through an interpreter. Most authors in this field, however, concur that faithfulness is the fundamental object of interpretation (8). My purpose in this paper is to explore the process of interpreter-interview assessment of psychopathology and to identify the major distortions that arise in this common practice. I will present specific recommendations to aid English-speaking clinicians who examine patients through an interpreter in minimizing errors.

METHOD

Two consecutive procedures were planned. The first included open discussions with psychiatrists and lay hospital interpreters who had experience in interpreter-interview evaluations. The second procedure, the main focus of the study, consisted of content analysis of audiotaped psychiatric interpreter-interview evaluations. For the first procedure, eight exclusively English-speaking psychiatrists and six bilingual hospital employees with extensive experience in interpreter interviews participated in unstructured discussions designed to obtain their impressions about problems in interpreter-interview examinations. In these dis-

Received July 26, 1977; revised Oct. 13, 1977, accepted Dec. 19, 1977.

Dr. Marcos is Associate Professor of Psychiatry, New York University School of Medicine, and Director, Department of Psychiatry, Gouverneur Hospital, 227 Madison St., New York, N.Y. 10002.

The author wishes to thank Anita Chin, R.N., Ms. Leah Lieberman, David Nemiroff, M.A., Manuel Trujillo, M.D., and the psychiatrists, lay hospital interpreters, and United Nations professional interpreters who contributed to this study.

This study was supported in part by Alcohol, Drug Abuse, and Mental Health Administration grant MH-08618 from the National Institute of Mental Health.

0002-953X/79/02/0171/04/$00.45 © 1979 American Psychiatric Association

cussions particular emphasis was placed on the following questions:

1. What are the general problems involved in the process of evaluating psychopathology through an interpreter?
2. What areas of mental status examination are more apt to be distorted by this procedure?
3. What are the ideal characteristics of interpreters who translate in a psychiatric interview?
4. What type of patients tend to have more difficulty adapting to this interview procedure?

For the second procedure, a total of eight psychiatric evaluations of non-English-speaking patients conducted through an interpreter were audiotaped for content analysis. The patients' native languages were Chinese or Spanish. They were seeking psychiatric help for a variety of emotional difficulties: two patients were diagnosed as suffering from involutional depression, two from depressive neurosis, and four from chronic undifferentiated schizophrenia. Their average age was 50 years. The patients had previously expressed willingness to volunteer for the study. An English-speaking psychiatrist conducted the interviews with the help of an interpreter. The English language questions were identical and were presented in the same order. The questions are the items of the Psychiatric Evaluation Form Interview (9), a distillate of the common probes used in psychiatric evaluations.

Three different types of lay interpreters who had no knowledge of the aims of the study participated in this procedure. Four interviews were interpreted by a psychiatric nurse with 10 years of experience in clinical psychiatry; two by a nurse's aide who was psychiatrically unsophisticated and worked in a different department, and two by the patients' relatives. All interpreters were proficient bilinguals, selected because they represented the type of individual commonly asked to participate as an interpreter in hospitals.

In the analysis of the recorded material, one English-Spanish and one English-Chinese bilingual psychiatrist listened to the respective audiotapes and compared the English portion with the Spanish or Chinese portion to assess their clinical equivalence. Specifically, these clinicians compared 1) the interviewing psychiatrist's questions with the interpreter's translation of them to the patient, and 2) the patient's answers with the interpreter's translation of them to the interviewing psychiatrist.

The clinicians who listened to the tapes were familiar with the conclusions of the first procedure (i.e., discussions with psychiatrists and lay hospital interpreters experienced in interpreter-mediated evaluations) and used those conclusions as the starting point in their comparative analysis. The rating clinicians were allowed to listen to the tapes as many times as they wished. Because this study was exploratory, no specific hypotheses were tested. The primary aim of this analysis was to identify patterns of distortions associated with the interpreter-interviewer procedure and with the different types of interpreters.

RESULTS

Psychiatrists' and Lay Interpreters' Views

General problems of interpreter-interv tions. All the psychiatrists who participate cussion agreed on frequent practical prob ated with the use of volunteer interpreter: preters often consider this practice "toc responsibility," an imposition, and a bot terruption of their regular job activities. T trists emphasized distortions stemming fr preter's attitude toward either the patient cian (e.g., an interpreter's overidentificat patient leading him or her to challenge th suggestions to the patient). Dynamics such terfere with the faithfulness of the interp create tension during the interview.

Most of the interpreters agreed that th embarrassed or anxious about some of th questions to the patient. These questions with sex, financial matters, and the explor cidal or homicidal tendencies. All of the felt overwhelmed by the responsibility o translators. Both psychiatrists and lay int pressed significant concern for the prote confidentiality of the patient's communic

Mental status evaluation through an Psychiatrists indicated that the assessme aspects of thinking and of affect (specifical al withdrawal and blunted affect) had a h bility of being distorted by the interpret dure. Also, certain ambivalent attitudes o the patient were difficult to evaluate th preters. Part of the problem appeared to translatable paralinguistic and vocal cue available to the clinician.

Characteristics of a good interpreter. believed that competence in both languag familiarity with the patient's culture we quirements. It was also suggested that the knowledge of clinical psychiatry could be minishing distortions, particularly in the a the formal aspect of thinking and affect. thought that as a rule patients' relatives o not make good interpreters because they l tivity.

Patients and the interpreter-interview With regard to the vulnerability of patients go these interviews, there was agreement t paranoid and very anxious patients usuall culty coping with the interpreter-intervie Some psychiatrists, however, suggested th patients who react positively to this prac they recognize in it extra interest and att

Analysis of the Recorded Interviews

The content analysis of the recorded in terview evaluations revealed a variety o that, in many instances, confirmed th pressed by the psychiatrists and lay in

eir previous discussions. The findings will be orgaed according to three major types.

1. Distortions associated with the interpreter's lantage competence and translation skills. Although, in neral, the interpreters were proficient in the source d target languages, various types of clinically relent errors of translation were detected. These includ omissions, additions, substitutions, and conensations. Such distortions appear to be related both insufficient language competence and to deficient inrpretative skills. Examples are given below.

Clinician to Chinese-speaking patient: "What kind of moods have you been in recently?"
Interpreter to patient: "How have you been feeling?"
Patient's response: "No, I don't have any more pain, my stomach is now fine, and I can eat much better since I take the medication."
Interpreter to clinician: "He says that he feels fine, no problems."

Clinician to Spanish-speaking patient: "Do you feel sad or blue, do you feel that life is not worthwhile sometimes?"
Interpreter to patient: "The doctor wants to know if you feel sad and if you like your life."
Patient's response: "No, yes, I know that my children need me, I cannot give up, I prefer not to think about it."
Interpreter to clinician: "She says that no, she says that she loves her children and that her children need her."

These examples were extracted from recorded interews conducted through psychiatrically unsophistited interpreters. In both cases it is obvious that the inician did not get an accurate impression of the paents' responses because of a combination of transtion errors such as omissions, condensations, and bstitutions. In the first case, the interpreter failed to mmunicate to the clinician that the patient had foused his response on his improved physical condition ther than his mood. In the second example, the paent's ambivalent answer about her feeling and life as not conveyed to the clinician. In fact, the intereter's translation indicated signs of tangential thinkg more than anything else.

Several distortions were also detected when the inrpreters attempted to translate patients' long anvers. Usually, interpreters' attempts to summarize swers resulted in a loss of important information.

2. Distortions associated with the interpreter's lack of ychiatric knowledge. The most frequent distortion in is category consisted of the interpreters' "normalation" of patients' thought disorders, such as circumstantiality, tangential thinking, loose associations, d blocking. It was obvious that interpreters often ied to "make sense" of the patients' disorganized atements, which prevented the clinician from detectg these important aspects of the mental status. The llowing verbatim example is self-explanatory:

Clinician to Spanish-speaking patient: "What about worries, do you have many worries?"
Interpreter to patient: "Is it there anything that bothers you?"
Patient's response: "I know, I know that God is with me, I'm not afraid, they cannot get me [pause] I'm wearing these new pants and I feel protected, I feel good, I don't get headaches anymore."
Interpreter to clinician: "He says that he is not afraid, he feels good, he doesn't have headaches anymore."

Also, as suggested in the discussions with psychiatrists and lay interpreters, the quality and depth of the patient's affect could not be assessed reliably through the interpreter. This may be related to the fact that interpreters tend to limit their translation to *what* the patient says, neglecting *how* the patient says it.

3. Distortions associated with the interpreter's attitudes. Interpreters who were relatives of the patient tended either to minimize or emphasize psychopathology. For example, the daughter of a patient clearly emphasized the patient's psychopathology while expressing to the clinician her belief that her mother should be hospitalized. In another instance the interpreter expressed to the patient his own negative feelings about the medication the clinician had just suggested. Because this was done in the patient's language, the clinician did not notice it. Similarly, in another interview the clinician was exploring the possibility of a tubal ligation with a patient, and the interpreter openly expressed her disagreement with this procedure and suggested that the patient not go along with it.

Another common observation was that relatives serving as interpreters answered the clinician's questions to the patient without actually asking the patient. For instance, the son of a patient was asked to inquire about his father's possible suicidal ideation. Without asking his father, he insisted on a negative answer.

DISCUSSION

The above findings suggest that clinicians evaluating non-English-speaking patients through an interpreter are confronted with consistent, clinically relevant, interpreter-related distortions which may give rise to important misconceptions about the patient's mental status. In addition to the relative untranslatability of some communicative components (e.g., the formal aspect of speech, expression of affect, and paralinguistic aspects), three major sources of interpretative distortions have been identified: 1) deficient linguistic and/or translation skills of the interpreter, 2) interpreters' lack of psychiatric sophistication, and 3) interpreters' attitudes toward either the patient or the clinician.

It would be optimal if there were enough competent psychiatric interpreters so that English-speaking clinicians could reliably evaluate non-English-speaking patients. Failing this, it is important that clinicians be made aware of the interpreter effect on the translation

of psychopathology. At this point some recommendations can be made to clinicians who must use the interpreter interview.

First, it is advisable that clinician and interpreter meet before the interview to discuss the goals of the evaluation, the focal areas to be assessed, and any particularly sensitive topic that may have to be explored (e g., suicidal or homicidal ideation, hospitalization, family relations). At this time, the clinician should make sure that the interpreter has an acceptable level of competence in the two languages. It is also important to explore the interpreter's attitude toward the interview and the patient, particularly when the interpreter is a relative or acquaintance of the patient or has expressed some preconceived ideas about the patient's problems. The clinician should also discuss confidentiality and emphasize the significant role of the interpreter as an objective intermediary in the evaluation process.

The clinician should make an extra effort to clarify for psychiatrically unsophisticated interpreters the differences between formal and content aspects of the patient's verbalizations (e.g., how the patient says things versus what the patient says). The need for textual translation should be emphasized, as well as the danger involved in attempting to "make sense" of the patient's statements. Interpreters should also be encouraged to ask for clarification from the patient or the clinician at any time during the interview.

Similarly, a postinterview meeting sho ranged between the clinician and the inte this session the clinician should look for clar both the interview material and the dynan interaction. Further, the interpreter shoul ample opportunity to verbalize and proces ings that may have been aroused during the i

ong-Term Effects of Traumatic War-Related Events on Sleep

Y PERETZ LAVIE, PH.D., ALBERT HEFEZ, M.D., GILA HALPERIN, M.SC., AND DANIEL ENOCH, M.D.

even patients who had combat neuroses resulting om the 1973 Yom Kippur War and complained of ep disturbances were studied in a sleep laboratory. eep-onset insomniacs, dream-interruption somniacs, and pseudoinsomniacs were fferentiated on the basis of electrophysiologic cordings. Compared with normal controls who tively participated in the Yom Kippur War, patients owed significantly longer sleep latencies, lower ep efficiency indices, lower percentage of REM ep, and longer REM latencies.

HE OCCURRENCE of sleep disturbances in the initial ages of the combat neurosis syndrome has been early established. Bartemeier and associates, in a de- led description of combat neurosis, wrote, "There almost unanimous agreement that the first symp- ns of the failure to maintain psychological equilibri- n are increasing irritability and disturbances of ep" (1, p. 374). Sleep disturbances included diffi- lties falling asleep and staying asleep, battle dreams, d recurrent terrifying dreams and nightmares. aigie (2), on the basis of 2 years' experience in the iddle East during World War II, listed insomnia as e fourth most common complaint of combat neurosis tients.

Less is known about the long-term effects of trau- atic war-related events on sleep. A group of 57 veter- s, studied 15 years after their combat experiences , showed a high incidence of insomnia and night ter- rs. In a follow-up study of 92 veterans of the Viet am War, it was found that their combat experience ntinued to disturb them long after they returned to vilian life—in some cases in the form of severe sleep sturbances (4). Another interesting finding emerged a follow-up study of survivors of marine explosions; ore of them complained of sleep disturbances 3.5–4.5 ars after the disaster than immediately following it (5). There is one report of a study of combat neurosis in a sleep laboratory in which electrophysiologic recording techniques were used (6). The authors reported that "in striking contrast to patients' reports of frequent nightmares prior to the study, only two clear nightmares were reported during the many nights of recordings" (pp. 30–31). This statement contradicts the nonlaboratory findings, which emphasized the role of nightmares and frequent battle dreams as the primary cause of sleep disturbances in combat neurosis patients. No other sleep disturbances were mentioned in that report.

In the present paper, we report sleep laboratory data on combat neurosis patients from the 1973 Yom Kippur War who were referred to our sleep laboratory with complaints of persistent sleep and/or emotional disturbances. An age-matched control group of active service veterans of the same war, who had been exposed to similar stresses but survived without psychological breakdown, was also studied.

METHOD

Subjects

Eleven patients, aged 24–33 years (mean=26.54, SD=3.35) were referred to the sleep laboratory 2–2.5 years after their traumatic experience. All of them were hospitalized during or shortly after the war for treatment of combat neurosis. Hospitalization periods ranged from 2 to 12 weeks, during which patients were given pharmacologic as well as psychotherapeutic treatment. None had a record of previous hospitalization or psychiatric treatments, and all claimed to have had normal sleep before the war. Nine of the 11 had been hospitalized after exposure to especially acute traumatic events, which in 5 cases were associated with physical injury. Patient 10, for instance, functioned normally for a week as a tank commander in the Sinai desert. Then his vehicle took a direct hit by an air-to-ground missile and he was thrown from the tank and suffered a head concussion. Emotional disturbances appeared while he was hospitalized for medical treatment, and psychiatric treatment was initiated.

In 2 patients neurotic symptoms appeared gradually over periods of weeks or months. Patient 3, for instance, served on the Golan Heights in a front-line technical unit that operated under stressful conditions. Five or 6 weeks after the cease-fire he began to exhibit neurotic symptoms—sleep disturbances, irritability,

depression, etc.—and was hospitalized in a psychiatric treatment center. All of the patients studied have received psychiatric treatment since the war.

In the psychiatric interviews before the sleep recordings, the most common complaints were depression, irritability, uncontrolled fits of rage, headaches, pain in various parts of the body, and sleep disturbances. The latter consisted of difficulty falling asleep, fragmented sleep, and frequent nightmares; in all cases, however, there had been considerable improvement since the war. Ten of the 11 patients had not been taking drugs for more than 2 weeks prior to the study. One patient used 5 mg of nitrazepam (Numbon) once or twice a week and no firm withdrawal period could be established, but since the sleep recordings showed no drug effects his data were included in the analysis.

Nine men aged 24–27 years were recruited from the Technion student body as controls. They were required to continue their normal everyday lives during the course of the study.

Sleep Recording Procedures

Patients and controls reported to the laboratory about an hour before their regular bedtimes and, except for 2 subjects whose observation continued for only 2 nights, slept in the laboratory 3 or 4 consecutive nights at a time. Totals of 34 and 27 nights were available for patients and controls, respectively. All participants were fitted with electrodes for recording EEGs, electro-oculograms (EOGs), electromyograms (EMGs), ECGs, and respiration (measured with a nostril thermistor and a respiratory belt); tibialis EMG was also recorded in some patients. All recordings were done on a Beckman type R411 dynograph according to established procedure (7). All sleep records were scored according to international criteria (7) in 30-second epochs. Data were averaged over all laboratory nights, excluding the first night, which was considered as adaptation to the laboratory. Data were averaged for the 2 subjects who were studied for 2 nights because no differences were found between the 2 nights.

The following parameters were extracted from each record: total time in bed; total sleep time; sleep latency; REM latency; percentages of sleep stages 1, 2, 3–4 (combined), REM, and wake time plus movement time after sleep onset; number of REM periods; length of first three REM periods; and length of the first and second sleep cycles measured from the beginning of one REM period to the beginning of the next one. Statistical significance of the differences between the 2 groups was assessed by two-tailed t tests.

RESULTS

Significant differences between patients and controls were found in REM latency ($p<.02$), REM percentage ($p<.002$), and length of the third REM period ($p<.04$). Total sleep time was shorter and sleep efficiency indices lower in patients than in contr ($p<.05$) (see table 1). According to the sleep efficier index, the patients fall into 2 subgroups (table 2): tients 1–5 had indices of 0.89 or more, sleep latenc of less than 15 minutes (mean=8 minutes), and l than 7% wake time after sleep onset plus movem time. Patients 6–11 had indices below 0.85, with mu longer sleep onset latencies (mean=41 minutes), a exhibited two types of sleep disturbances. In 2 of t latter group (patients 10 and 11), the low index v primarily due to a large increase in wake time a sleep onset, accumulated in multiple mid-sleep aw enings. The remaining patients in the subgroup exh ited long sleep latencies with few mid-sleep aw enings. The hypnograms in figure 1 demonstrate t different types of sleep disturbances and indicate a that most mid-sleep awakenings in patient 10 cluste around REM periods or at expected times of REM riods. A similar temporal pattern of mid-sleep aw enings was observed in patient 11. These repetitive terruptions of REM sleep suggest that patients 10 a 11 suffered from dream-interruption insomnia (8). F ther evidence is provided by the fact that they were only ones to report war-related nightmares on aw ening from REM sleep in the laboratory. Moreov most REM interruptions were preceded by increa heart rate. Similar relationships between autonor arousal and REM nightmares were described by Fi er and associates (9).

ep Hypnograms of Sleep-Onset Insomnia (Patient 9) and Dream-
rruption Insomnia (Patient 10)

ting. Patient 3 manifested an interesting variant of eep disturbances. In the preliminary interview he ade no mention of actual sleep disturbances but complained of severe fatigue and dizziness in the morning iat often persisted throughout the day. Sleep recordgs revealed an apparently normal amount of sleep, ith an index of 93.0, but there were an unusual numer of gross body movements, averaging 0.20/minute ver his 3 recording nights. On the third night, after he entioned occasionally waking up with "aching legs," bialis EMG recordings were taken and revealed myonic jerking of the legs at a rate of about 1/minute uring the first 3 hours of sleep. These leg movements did not interfere with the sleep process, which was predominantly of stages 3 and 4. Two other patients revealed similar rates of body movement, and both had indices higher than 0.88.

In 4 patients, the recordings indicated modifications toward a more aroused sleep. Patients 10 and 11, who had multiple mid-REM awakenings, also exhibited during sleep stage 2 and REM sleep frequent trains of alpha activity that persisted for 2–5 seconds and differed from the alpha-delta sleep pattern observed earlier in psychiatric patients (10). Similar alpha trains were observed in a third patient with a sleep-onset insomnia; a fourth patient demonstrated a dramatic increase in the rate of K complexes during sleep stage 2: 2.72, 1.60, 2.59, and 2.59 per minute for the 4 recording nights, respectively, compared with the mean rate of 1.21/minute reported for normal individuals of similar age (11).

None of the controls exhibited similar sleep modifications. A detailed comparative study of some of these episodic sleep phenomena between patients and controls is currently being done in our laboratory.

DISCUSSION

Our investigation demonstrated that exposure to traumatic events which lead to psychological breakdown has long-term effects on sleep; these could be detected in the laboratory 2 to 2.5 years after the trauma. Like insomnia in general the combat neurosis version studied here was a combination of sleep-onset insomnia, dream-interruption insomnia, nocturnal myoclonus, and pseudoinsomnia. It is not certain, however, whether all 5 patients whose sleep was adequate were actually pseudoinsomniacs. The high rate of nocturnal body movements observed in 3 of these patients (who complained of fatigue on awakening in the morning, usually persisting throughout the day) suggests that classification as a nonrestorative sleep syndrome is more appropriate in this case. The in-

crease in nocturnal motor activity may represent a basic disturbance of the sleep process that is not reflected in changes in sleep architecture. Unaware of their increase in motor behavior, the patients misattributed their morning feeling to increased sleep latency and mid-sleep awakenings. Takahashi and associates (12) also reported increased rates of body movements in pseudoinsomniacs. It should be emphasized, however, that based on patients' complaints in prerecording interviews, patients 1–5 could not be differentiated from patients 6–11.

The reduced REM percentages and increased REM latencies in this sample are surprising, since most patients complained of emotional dreams and of occasional nightmares. The possibility that the reduced REM time was an artifact of short sleep periods or was secondary to depression can be ruled out, since patients and controls with matched sleep periods differed significantly in REM time, and patients free of any depressive symptoms showed reduced REM time. Although we have no immediate explanation for the reduced REM time on the basis of existing literature data, it might be a means of forestalling highly emotional dreams. Except for 2 patients with dream-interruption insomnia, none of the subjects reported nightmares in the laboratory; all of them spoke of almost nightly nightmares immediately following the trauma, and some described forcing themselves to stay awake to avoid recurrent terrifying dreams. If this is the case, dynamic changes in REM sleep parameters should be found at different times after the trauma, and patients who have completely recovered should have norm near normal amounts of REM sleep. These quest are still open.

ersonality, Sexual Adjustment, and Brain Lesions in Patients ith Conversion Symptoms

HAROLD MERSKEY, D.M., AND MICHAEL TRIMBLE, M.B., M.PHIL.

clarify the interrelationships of conversion nptoms, hysterical personality, sexual adjustment, d cerebral organic disorders the authors studied 89 tients with classic motor conversion symptoms oup L) and compared a subgroup of 24 of these tients (group H) with 24 matched control patients oup C). They found hysterical personality in 19% of ɔup L, 21% of group H, and none of group C and ssive-immature-dependent personality in 19% of ɔup L, 21% of group H, and none of group C. Forty-ht percent of group L, 50% of group H, and 58% of ɔup C had some cerebral disorder. Patients with nversion symptoms who also had hysterical and ssive-immature-dependent personalities were ɔecially likely to have sexual abnormalities.

PARTICULAR, DRAMATIC TYPE of personality has ditionally been associated with hysterical symptoms. aepelin (1) and Lewis (2) have provided vivid deriptions of this type. Chodoff and Lyons (3), hower, pointed out that the "so-called hysterical consrsion reactions do not occur solely by any means in tients who present the characteristics of the hysical personality." De Alarcon (4) criticized Chodoff d Lyons and others who reached similar conclusions the grounds that their studies were retrospective. e Alarcon observed, "It may be safe to assume that obably all patients with symptoms of hysteria have me features of what we call hysterical personality." e demonstrated that in 14 papers on hysteria, includg that of Chodoff and Lyons, the following characristics were repeatedly mentioned for the hysterical rsonality: histrionic behavior, egocentricity, emoɔnal lability, dependency, excitability, seductivess, suggestibility, and childishness. Lazare and asciates (5) further demonstrated that features of the sterical personality, as defined in the literature, can discriminated in psychiatric patients. There is thus od evidence that hysterical personality has definable features that may have demonstrable psychogenetic characteristics.

Conversion symptoms were explained by Breuer and Freud (6) as the consequence of unconscious sexual conflict. Wartime experiences led to the view that conflicts other than sexual ones might be responsible for such symptoms (7). There have been very few reports recording the frequency of impairment of sexual relationships in patients with hysteria. Purtell and associates (8) studied 50 patients with hysteria and reported that 86% of them showed sexual indifference and 73% had no pleasure from sexual activity. They also stated that 98% of their women patients with hysteria had some kind of sexual symptom and that the most common was indifference.

The definition of hysteria of Purtell and associates, as well as that of Perley and Guze (9) and that of Winokur and Leonard (10), conforms to Guze's definition (11), which involves patients who are a different population from those who have conversion symptoms only. It was the latter who were the subjects of the classical observations of Charcot (12) and Breuer and Freud (6) and in whom a link between the symptom and sexual repression was first implied. Further, although it is generally accepted that fear of sexuality is one factor in the hysterical personality, there are few hard data to support this view apart from some experimental observations in students (13–15).

Other work (16–18) has suggested that cerebral organic disease has a role in causing hysterical symptoms. The interrelationships of conversion symptoms, hysterical personality, sexual adjustment, and cerebral organic disorders remains unsettled. In this paper we record evidence regarding the link between personality and sexual maladjustment in 89 patients with conversion symptoms. We compare a subgroup of patients with conversion symptoms with matched psychiatric patient control subjects. We also examine the relationship between conversion symptoms and personality and the presence of cerebral organic disorders.

METHOD

The 89 patients with conversion symptoms (group L) reported on here comprise a series of personal cases seen by one of us (H.M.) at the National Hospitals for Nervous Diseases at Queen Square and at Maida

ceived Jan. 31, 1977; revised May 24, 1977; accepted June 29, 77.

. Merskey is Professor of Psychiatry, University of Western Onio and London Psychiatric Hospital, 850 Highbury Ave., P.O. x 2532, Terminal A, London, Ont., Canada N6A 4H1. Dr. imble is Physician in Psychological Medicine, National Hospital Nervous Diseases, Queen Square, London, England.

0002-953X/79/02/0179/04/$00.45 © 1979 American Psychiatric Association

Vale between September 1968 and December 1971. Details of the selection of these patients as well as details of the selection of the control group of psychiatric patients matched for age and sex with 24 of the 89 index cases were given in 1975 by Merskey and Buhrich (18). The subgroup of 24 patients with conversion symptoms matched for age and sex to the control group is referred to as group H, and the control group is referred to as group C.

Forty-eight percent of group L, 50% of group H, and 58% of group C had some cerebral lesion or disorder affecting cerebral function. The most common of these was epilepsy (23 in group L, 5 in group H, and 8 in group C). Others included multiple sclerosis, cerebrovascular disease, tumor, head injury, encephalitis, and dementia. The high proportion of patients in group C with physical illness is partly explained by the fact that the Department of Psychiatry at the National Hospitals provides psychiatric service to neurological patients. However, this factor does not entirely account for the high proportion of organically ill patients in group L and group H because many of the patients in these groups might have been expected to have been referred for differential diagnosis of somatic symptoms.

During the course of examination of these patients the personality characteristics of each one as well as information about sexual adjustment were recorded. Patients were regarded as having a hysterical personality on the basis of attention-seeking, histrionic, and emotionally labile attitudes, with or without seductiveness. Frigidity or sexual maladjustment were not included in the criteria for hysterical personality because they were being compared with hysterical personality traits. Obsessional personalities were defined as those who adopted meticulous patterns of behavior, usually with minor checking habits. Passive-immature-dependent personalities were defined as those who showed childish, immature attitudes, a lack of independent behavior in social and personal relationships, and overt dependence on others in their family and immediate environment. These gradings were essentially the systematic personal judgments of one of us (H.M.). Other characteristics graded were the anxious, worrying personality type, psychopathic personality, and a variety of mild character deviations.

Sixteen patients showed no evidence of any definite personality deviation; these patients are referred to in the study as "normal." The group labeled hysterical were compared with the subgroups labeled, respectively, obsessional, passive-immature-dependent, and "normal."

The patients' sexual behavior was graded into the five following categories:

Category 1: frigidity includes all patients who said they never fully enjoyed sexual intercourse or that they had refused it despite reasonable opportunity and lack of moral objection.

Category 2: life-long abstention refers to patients over the age of 40 who had lived an inhibited life, having refused opportunities for heterosexual relatic ships, marriage, or both.

Category 3: current problem includes patients wl had been sexually normal but who expressed a curre problem of loss of interest, loss of enjoyment, or imp tence.

Category 4: normal includes unmarried patients u der the age of 40 who were interested in heterosexu contacts, enjoyed sexual intercourse, had hete sexual masturbation fantasies, or dated; it also i cludes married patients who enjoyed intercourse.

Category 5: insufficient information includes p tients for whom relevant information was scanty b cause of their circumstances or who were reticent providing information.

We recognize that these criteria are conservati and may have reduced the percentages of abnormal recorded.

RESULTS

Of 89 patients with conversion symptoms (group I 16 (17%) were men and 73 (83%) were women. T number of patients with hysterical, obsessional, pa sive-immature-dependent, and "normal" personal styles in group L and in the 24 control patients in gro C are shown in table 1. Results are also given for t subgroup of patients with conversion sympto (group H) compared with the control group.

There was a significant excess of hysterical perso ality and passive-immature-dependent personality the group of patients with conversion hysteria co

ie differences were not significant.

red with control patients (see table 1). One male and females in group L had hysterical personality (age nge 17–65, mean 36.9), 1 male and 16 females had ssive-immature-dependent personality (age range –56, mean 38.4); and 1 male and 6 females had obssional personalities (age range 15–60, mean 33.4). ven males and 9 females (age range 16–60, mean .9) were considered "normal."

The results of our ratings of the sexual behavior of e total sample are shown in table 2. This table shows e number and percentage of patients reporting nor-al (category 4) and abnormal (categories 1–3) sexual justment. Thirty-two percent of the patients with nversion hysteria had abnormal sexual adjustment. ie difference between groups H and C was signifi-nt (see table 2).

Ratings of sexual behavior in relation to personality yles are shown in table 3. The sexual maladjustment patients in the group with hysterical personality was gnificantly greater than that of patients in the "nor-al" group (see table 3). There was a greater in-dence of reported sexual abnormality in the passive-mature-dependent group than in the "normal" oup, but this difference did not reach significant lev-s. There was also a trend toward greater sexual ab-rmality in the hysterical group compared with the sessional group (59% and 29%, respectively).

In the hysterical personality group 7 of 10 of the patients reporting abnormal sexual adjustment reported life-long frigidity; 2 of 10 were life-long abstainers. In the passive-immature-dependent group 7 of 8 reported life-long frigidity. In both groups there was 1 patient with a current problem. In the obsessional group 1 patient had current problems and 1 reported frigidity. In the "normal" group 1 patient reported life-long frigidity and 2 reported a current problem. The higher incidence of sexual abnormality in patients with conversion hysteria (see table 2) is attributable to frigidity, and this is particularly related to passive-immature-dependent and hysterical personality patterns.

We examined the presence of chronic organic disorders affecting the CNS in relation to both personality style and sexual behavior. Details of the organic illnesses were provided in 1975 by Merskey and Buhrich (18). As already mentioned, the largest number of patients with such disorders had epilepsy. The 23 patients with epilepsy were grouped with another 16 patients who had organic CNS disorders affecting the upper brain stem or higher levels. Twenty-four of these 39 patients reported normal sexual adjustment, and 10 reported abnormal sexual adjustment. Among 40 patients with no organic pathology, 19 had normal sexual adjustment and 17 had abnormal sexual adjustment. The trend for organically sick patients to have better sexual adjustment was not significant. There was also no significant difference between patients with epilepsy and others with organic lesions or between those with definite temporal lobe epilepsy and the rest of the epileptic subjects. The distribution of personality patterns in those with epilepsy was similar to the whole group with conversion symptoms.

Table 4 shows the incidence of organic pathology in the different personality groups. Obsessional patients were more likely than hysterical patients to have an organic lesion, but the numbers are few and the trend is weak.

DISCUSSION

Of 89 patients with conversion symptoms, 19% had a hysterical personality style. This figure approximates that cited by Chodoff and Lyons (3) (3 of 17 of their series) and that of Ljungberg (19), who cited a figure of 21% for his series, a figure that Slater (16) also cited for his patients. Thus, conversion hysteria is not uniformly related to a hysterical personality style. However, our figures show that the incidence of hysterical personality in patients with conversion symptoms is considerably higher than in a control population. This supports the contention that the hysterical personality style is more likely to lead to conversion reactions, although they need not be expected in every patient with hysterical personality.

We have also found an equal incidence of passive-immature-dependent personality in patients with conversion symptoms. This finding and the fact that there is a much smaller proportion of obsessional patients in

the group with conversion symptoms compared with control subjects suggest that patients with conversion symptoms have personality characteristics that differ from those of other psychiatric patients.

Analysis of the sexual adjustment of the patients with conversion reactions indicates that 58% of the total group with conversion symptoms and 54% of the subgroup of these patients reported normal adjustment. This is significantly different from the 83% of normally adjusted patients in the control population of psychiatric patients. The comparative increase in the incidence of abnormal sexual adjustment in conversion hysteria in this series does not appear to be related to the presence of organic factors. It is also far less than that cited by Purtell and associates (8) (86%). With broader criteria we might have found a larger incidence of sexual abnormality, but we believe that the population of Purtell and associates was different from ours and that ours is perhaps the first controlled demonstration of sexual pathology in patients suffering from conversion hysteria. This facet of abnormal behavior is not confined to patients with hysterical personality. Patients with passive-immature-dependent personalities also had a high incidence of sexual maladjustment. Both groups had frigidity as the common abnormality. The characteristics of the passive-immature-dependent personality style are equivalent to those designated "oral" by Lazare and associates (5), who reported that "dependency, passivity, self-doubt, fear of sexuality appear in the oral factor."

The fact that 58% of our patients reported normal sexual adjustment suggests that the etiology of conversion symptoms is not invariably a "substitute for sexual gratification," as would be predicted by Freudian libido theory (20). We would therefore agree to some extent with Chodoff (21) that

> however these disorders are labeled, miscarried sexuality probably does not play the major role in their psychogenesis, for our epoch at least. It appears that failed human needs and strivings other than the sexual ones are responsible for the strange symptoms and desperate lifestyles that have been called hysterical.

Personality disorders and sexual maladjustment remain important correlates of conversion symptoms. In addition, organic lesions were slightly more frequent in patients with conversion symptoms and obsessional personality. Thus, the genesis of conversion symptoms is multifactorial. In settled conditions in developed countries they are infrequent except in certain special settings, e.g., a neurological clinic (18). They will be more likely to occur in association with the hysterical personality, sexual maladjustment, or chronic brain lesions.

The further theoretical significance of these differe causes still remains to be evaluated, although Wh lock (17) has pointed out that no theory of hyste which fails to take into account both psychological a organic causes can be adequate. We can conclude th personality factors, sexual maladjustment, situatio problems, and organic cerebral disease all play su stantial roles that are sometimes complementary a sometimes independent in the production of co version symptoms.

sychiatric Services in Soviet General Outpatient Clinics

Y BORIS M. SEGAL, M.D.

e author believes that the first level of psychiatric re in the U.S.S.R.—the general polyclinics utpatient clinics) and the medical-sanitary units— ve not been adequately studied. He describes this el of care, which is considered useful and ogressive in that the clinics are supposed to make ychiatric care available to the population, lighten e load placed on psychiatric facilities, and improve llow-up therapy. However, he also points out the ortcomings in this first level of psychiatric care in e U.S.S.R., including the bureaucratic nature of the stem and the uneven quality of service the clinics nder to various social groups in urban and rural eas.

ESTERN WRITERS (1–17) as well as Soviet writers 3–29) have described the concepts, structure, and livery system of psychiatric services in the U.S.S.R. owever, the majority of these works analyzed the acities of psychiatric dispensaries (community mental alth centers) and mental hospitals—the second and ird levels of psychiatric service. The first level of ch medical aid has not yet been adequately studied. According to official Soviet sources (18–29), social- d health care in the U.S.S.R. has two important funcns: the curative-prophylactic and the sanitary-hyenic. The curative-prophylactic aspect of medical aid the responsibility of district and special polyclinics utpatient clinics) and of psychiatric, venereological, ncer, and tuberculosis dispensaries as well as varis kinds of hospitals. There are also medical-sanitary nters (health units) and a special network of medical cilities for children that includes polyclinics, hospils, and consultation clinics. There are also consultan clinics for women.

IMARY CARE FACILITIES

neral Polyclinics

The first level of general medical care in urban areas the district (*raion*) polyclinic (outpatient clinic). In large cities these facilities usually serve approximately 40,000 residents. Service is available only to individuals registered in a given district. Consultation in the polyclinic is available with internists and with such specialists as surgeons, neuropathologists (or psychoneurologists, neurologists with some training in psychiatry), ophthalmologists, and ear specialists. There are also therapy rooms for surgery, physiotherapy, and other forms of treatment. The entire population of a district is divided into smaller districts (*uchastki*), and each of these smaller districts is served by a physician who not only receives patients during appointed hours but who also makes house calls to patients unable to get to a medical office. Such a district in a large city may contain 3,000–4,000 inhabitants. Polyclinic physicians prescribe treatment for patients, send them to a hospital if necessary, care for them after they are discharged from the hospital, arrange for consultations with specialists, sign releases from work, and direct patients to a pension commission.

The task of the polyclinic is not only therapeutic but also preventive. The polyclinic must actively seek patients who need treatment; it must act to prevent illness among the population of its precinct. Once or twice a year it must conduct examinations of patients with suspected or confirmed serious disorders. Most of the polyclinics do not have regularly employed psychiatrists. According to official data, consultations with patients who exhibit signs of such so-called border conditions as neuroses or psychosomatic disorders are conducted by a neuropathologist or psychoneurologist. The local district physician—an internist—and the neuropathologist are supposed to locate mentally ill patients within their area and direct them to the district psychiatric health center (dispensary). Certain large district polyclinics require a psychiatrist from the district psychiatric health center to hold periodic consultations, thus facilitating the discovery of early and mild forms of mental illness.

The larger *raion* polyclinic keeps a file on every patient discharged from a psychiatric hospital, thus enabling the physician in a small district facility to maintain contact with local psychiatrists if necessary.

Other Facilities

The medical-sanitary centers have the same functions as do polyclinics, but their activity is directly connected to a specific enterprise or a factory. When these centers were organized after the revolution, their task was to improve medical services for workers.

ceived March 31, 1975; revised July 7, 1975, April 4, 1978; accept- Aug. 23, 1978.

. Segal is with Metropolitan State Hospital, Waltham, Mass. 154.

0002-953X/79/02/0183/04/$00.45 © 1979 American Psychiatric Association

Large medical-sanitary centers have qualified personnel, special hospitals, and sanatoriums at their disposal. Normally, no psychiatrists are employed in these facilities, but large medical sanitary centers have a psychiatric unit, sometimes on a part-time basis. Neuropathologists also work in these facilities, and they are supposed to conduct therapeutic as well as preventive work.

There is also an extensive network of departmental medico-sanitary centers and clinics. Many ministries, the academies, the KGB, and "creative" unions (unions of writers, composers, architects, and others) have special "closed" clinics serving only employees and their families. The many military research institutes or so-called numbered enterprises have their own "closed" medical-sanitary centers and hospitals.

Rural Areas

The first links in the chain of medical psychiatric care in rural areas are the psychoneurologist who works in the district polyclinic, the rural precinct physicians, and the feldshers. Rural physicians or feldshers send patients who have recently become ill or whose condition has become more acute to the district polyclinic or regional psychiatric health outpatient clinic. This facility, along with the regional interdistrict psychiatric hospital, is supposed to provide systematic care, periodically sending patients for consultations with psychatrists in the district. According to official literature (19, 20, 27–29), when a consulting psychiatrist arrives in a rural district he or she studies patients, checks the status of the register, notes corrections that must be introduced in the files of the regional outpatient clinic (e.g., a change in diagnosis), and recommends treatment and work arrangements. The same sort of instructive-consultative work is to be done on a higher level by the psychiatrist in the district polyclinic attached to the office of the psychoneurologist.

Rural district physicians are supposed to do more than just study the condition of the mentally ill and to hospitalize them. They are also to provide follow-up therapy for patients who have been discharged from the hospital that will enable them to return to work. Soviet authors (27–29) have recommended outpatient treatment in rural areas for a large number of patients with epilepsy and organic diseases of the brain, for alcoholics, and for mentally retarded patients. Precinct doctors are supposed to provide care to schizophrenic patients in remission, to patients with residual paranoid ideas, to those with acute but short-term psychotic disorders of a toxic-infectious nature, those with postseizure conditions, and those with an acute alcoholic abstinence syndrome (27–29).

In sum, the official data (18–29) describe a well-organized and universal system of preliminary outpatient care for mental patients in the U.S.S.R. However, the first level of mental health services corresponds to the hierarchical structure of Soviet society rather than to this model.

PROBLEMS IN PRIMARY CARE

The medical facilities for the elite in Soviet soci offer the most favorable conditions. The "close polyclinics for the privileged are well equipped and located in attractive and modern buildings. The sp cialists employed by these establishments are selec with special care. The number of patients in these c ics is much smaller than in the general polyclinics, the attending physician and psychoneurologist (or p chiatrist) spends a considerable amount of time exa ining patients. Preventive and psychotherapeuti work in these institutions corresponds to the model scribed above. Patients are regularly reexamined ev if they do not request medical care. Consultations available with prominent specialists. Patients in ne of additional care are directed to research institutio departmental sanatoriums, rest homes, and spec hospitals.

The higher party and government officials are serv by polyclinics of the special administration of the M istry of Health. These closely guarded "Kremli polyclinics enjoy the most privileged position. The s aries of the physicians and staff in these facilities 50% above the norm, and the staff are given a numb of privileges. Their relations with the patients strictly controlled by the administration. Patients offered all of the modern methods of examination a treatment and all the services of a family doctor.

Large cities also have an extensive network of f and accessible district polyclinics and medical-sa tary centers. In general, this system provides the ur population with more or less adequate medical se ice. The main shortcoming of the system—one tha peculiar to all medical care in the U.S.S.R.—is the for bureaucratic nature of the work. The psych neurologist, like the physician in a polyclinic, is ti and dissatisfied with overwork and extremely low p (the general salary for this work is approximately 1 150 rubles or $130–$200 a month). The physic spends a major part of his or her workday filling various documents; almost no time is left for exam ing and talking with patients.

Patients correctly complain that appointments in polyclinic often result in nothing more than receivin work release form. The atmosphere of polyclinics usually tense. There are long lines of people waiting see doctors. It is very difficult to meet with hig qualified psychiatrists. Many patients try to rece private treatment even though this is officially forb den.

Local psychoneurologists in small districts are in especially difficult position; they view their work exhausting and thankless. They do not provide p ventive treatment, but they make house calls. C sultations with psychiatrists in district polyclinics rare; there is little or no prophylactic or therapeu work conducted among patients with neuroses or w psychosomatic and sexual disorders, although su patients account for a substantial number of appo

ents. These patients receive only mild tranquilizers d are advised to "not be nervous." In fact, there are) facilities for such patients. They are usually not nt to psychiatric outpatient clinics because they are)t sick enough. They are told, "They're crazy there. 'hat do you want to go there for?" If those seeking :lp do manage to get an appointment with a psychia- .st, most frequently the result is just a short chat and prescription for tranquilizers. For patients with more rious neurotic disorders there are psychotherapy oups in some psychiatric dispensaries. Psychotic pa- nts are sent to psychiatric dispensaries.

The availability of psychiatric service in small cities d especially in villages presents a problem that is far om being solved. There are usually one or two poly- nics in small cities but no psychiatrist and no neuro- thologist. To obtain an appointment with these spe- alists one usually has to travel some distance to the gional center, which is often located several hundred lometers away. Because of poor travel connections, lack of good roads (especially in the spring and fall hen weather conditions make it almost impossible to t anywhere), and the lack of privately owned autos, e journey to a medical center can be very difficult. elatives of patients with psychomotor agitation en- unter the most distressing problems. Families are ten forced to make great financial sacrifices to obtain car and get the patient to the regional center. Villages nerally have no ambulances for psychiatric cases, d the police refuse to transport the mentally ill.

Doctors do not accept patients from other regions ecause medical practice in the U.S.S.R. requires at patients be treated according to their place of sidence, that is, where they are registered by the po- ce. Unless they have made previous agreements with eir superiors, local doctors are categorically for- dden to issue their patients permits to travel to rge cities where there are more qualified psychia- ists and where there is usually a better organized stem of health service. In spite of all these bar- ers many patients travel without permits to Moscow, eningrad, Kiev, and other large cities. On arriving in ny one of these centers, they are sent to the Ministry f Health and to other official departments, where they ceive assignments with recommendations that they e examined and treated according to their place of sidence. Only in certain instances does the Ministry ermit a patient from the provinces to be examined in n outpatient clinic of the capital, and very rarely is ch a patient hospitalized in a big city. This usually ppens only if the patient's relatives have made sev- al complaints to higher officials and Party depart- ents. Sometimes, in desperation, patients and their elatives refuse to travel to their place of residence. hey demand justice, creating a public disturbance to ring attention to their case.

Thus, complex bureaucratic obstacles hamper the rst level of mental service in the U.S.S.R. An extensive stem of barriers prevents the population from taking dvantage of socialized medical care. The many mil- ions of rural inhabitants receive the least favorable treatment and are in the most difficult position. (One must take into consideration that in 1970 44% of the Soviet population lived in rural areas; an additional 47,500,000 people lived in small cities.) In addition, the supply of medicine, which is generally poor throughout the U.S.S.R., is especially inadequate in rural pharmacies, where there are no psychopharmacological remedies. All these problems create a dissatisfaction with the system of medical care—especially among the lower strata of the population.

Early Review of Annual Meeting Papers

The *Journal* will continue this year its policy of early review of annual meeting papers. Final versions of papers that are ready before the Chicago meeting will be accepted for review. Do *not* submit your paper early if you anticipate substantive revisions after discussion at the meeting. Manuscripts should be submitted in triplicate, double-spaced throughout, and prepared in conformance with *Journal* style specifications, including length limitations. Papers written in "speech" format should not be submitted.

Please label the paper "Annual Meeting 1979, Final Version" and include on the title page the address and phone number of the corresponding author and the number of words, tables, and figures. The cover letter should incorporate the copyright transfer statement described in "Information for Contributors."

Since the *Journal* has first refusal rights for annual meeting papers, it is necessary to obtain the Editor's permission before submitting a paper elsewhere.

If your paper will not be ready for review before the meeting but will be in final form at that time, bring three copies to Chicago and submit them to the session Secretary (submitting copies to the Press Office *does not* satisfy this requirement). Again, papers that are not ready for review should not be given to the Secretary.

If you have questions about this or other *Journal* policies, please stop by the *American Journal of Psychiatry* staff office during the meeting, and staff members will be pleased to assist you.

RIEF COMMUNICATIONS

orazepam, a New Benzodiazepine Derivative, in the Treatment f Anxiety: A Double-Blind Clinical Evaluation

C LAYTON MCCURDY, M.D.

nety-five adult outpatients suffering from moderate severe anxiety were randomly assigned to treatment th lorazepam or placebo in a double-blind four-week dy. Patients were evaluated at pretreatment and er two and four weeks of treatment using three ing scales. Lorazepam, at an average daily dose of mg twice daily, was highly effective in relieving xiety as documented by clinically and statistically nificant differences over placebo in most of the ms on all rating scales at all rating periods. No rious adverse effects were reported, and there were adverse interactions with other medications, cluding digitalis and aspirin.

HERE HAS LONG been public and medical concern th the alleviation of excessive anxiety. This interest s resulted in extensive research to determine the uses of anxiety, design methods for evaluating it, d develop therapies for its treatment. Drugs, in par- ular the benzodiazepine derivatives, have proven to a successful therapeutic modality. These com- unds have been under continuing development and finement since the 1960s (1).

Lorazepam, or 7-chloro-5-(*o*-chlorophenyl)-1,3-di- dro-3-hydroxy-2H-1,4-benzodiazepin-2-one, one of e newer benzodiazepine compounds, is generally ell tolerated, has a low biological toxicity (2), and oduces few side effects (3–5). On a weight basis, lorazepam is a more active anxiolytic than diazepam (1 mg versus 5 mg, respectively). While this drug is relatively new to the United States, it has been widely used in other parts of the world, particularly Europe.

The following double-blind study was conducted to assess the efficacy and safety of lorazepam in treating anxiety.

METHOD

Ninety-five patients, 35 men and 60 women ranging in age from 18 to 65 years, participated in the study. These patients were referred from a community mental health center and an Alcoholics Anonymous group. They represented a broad range of socioeconomic backgrounds.

Selection criteria required that all patients have ratings of at least moderately severe anxiety as well as three related symptoms on the Hamilton Anxiety Scale (6). They were also required to have a global rating of at least moderate illness. Patients excluded from the study consisted of those with signs of psychosis or a history of psychosis, acute or chronic brain syndrome, mental deficiency, acute reactive or involutional depression, suicidal tendencies, and drug addiction. Patients with a sensitivity to benzodiazepines were also excluded, as were pregnant patients and those with a history of myocardial infarction within 3 months of the study. Patients suffering from alcoholism were included in the study if they met the above criteria and had been sober for 60 days. Informed consent was obtained before patients were accepted into the study group. Patients were permitted no psychoactive medication for at least 4 days before the study began.

The study design was fully randomized and was double-blind. The total duration of the study was 4 weeks; patients were evaluated at pretreatment and after 2 and 4 weeks of treatment. Patients received either

1-mg scored tablets of lorazepam or matching placebo, administered on a twice-daily schedule. All but 1 patient started on a regimen of 3 tablets per day, 1 in the morning and 2 at bedtime. If there was a need to reduce the dosage, the morning dose was eliminated first. After the first follow-up visit (at 2 weeks), the daily dosage was continued, reduced, or increased to a maximum of 6 tablets per day, maintaining the twice-daily regimen.

The 95 participants were randomly divided into 2 groups. Forty-seven patients received lorazepam and 48 received placebo. Efficacy and safety were evaluated after 2 and 4 weeks of treatment and at a final evaluation, which by protocol was defined as the last evaluation for any patient who participated in the study for at least 4 days. Although 16 patients (5 in the lorazepam group and 11 in the placebo group) failed to complete the full 4-week course of treatment, 87 (43 in the lorazepam group and 44 in the placebo group) were available for final evaluation.

The efficacy of medication was measured using a global rating scale, the physician-administered Hamilton Anxiety Rating Scale (6), and the self-administered Lipman-Rickels 35-Item Self-Rating Scale (7). The global assessment of the severity of illness used a 4-point scale, while the degree of change since the start of the study was judged on a 7-point scale. The Hamilton Anxiety Rating Scale measured drug effectiveness through changes in total scores in 13 symptom categories, and in psychic and somatic clusters. Intensity of symptoms was rated on a 5-point scale (1=absent, 2=mild, 3=moderate, 4=severe, and 5=very severe). The Lipman-Rickels scale was used to determine therapeutic effectiveness.

At each visit patients were asked whether there were any side effects and, if so, their nature and intensity. In order to avoid prompting the patients, the questions were asked without resort to a checklist. All adverse side effects were recorded regardless of the patient's ultimate inclusion in or exclusion from the efficacy evaluation.

One-way analysis of variance, chi-square test of independence, and Fisher exact probability test were used to determine whether the 2 treatment groups were initially balanced and homogeneous in terms of severity of illness and demographic characteristics. Because of their subjective, ordinal nature the rating scale data were evaluated by means of nonparametric statistical tests. The Kruskal-Wallis test was applied to scores from all three rating scales to compare drug efficacy between treatment groups. Fisher's exact probability test was applied to changes in the global ratings after pretreatment to detect differences between groups.

RESULTS

There were no significant differences between the 2 treatment groups in age, weight, race, sex, duration of illness, or initial severity of illness on the global, Hamilton, and self-rating scales. Four patients from each group were excluded from the final efficacy evaluations because rating scale data were incomplete or not obtained, leaving 43 in the lorazepam group and 44 in the placebo group available for final evaluation.

Dosage

Total daily dosages of lorazepam ranged from 2 to 6 mg, with a mean of 3.2 mg; the mean treatment period was 26.5 days. Dosages in the placebo group ranged from 3 to 6 tablets per day, with a mean of 3.4; the mean treatment period was 24.6 days. At the end of 2 weeks 38% of the patients were receiving an increased dosage of lorazepam (i.e., over 3 mg per day), and 51% required an increased dosage of placebo.

Clinical Efficacy Ratios

According to published standards for evaluating psychotropic drugs (8), a drug can be regarded as demonstrating clinically significant efficacy if the percentage of patients improved with the drug divided by the percentage improved with placebo is at least 1.5. Clinical efficacy ratios may be determined on the basis of the percent of patients improved, percent reduction in mean scores on rating scales, or both. Both types of ratios were computed in this study.

Table 1 presents the overall improvement rates (percent of patients improved) for the three rating scales at the final evaluation. There was a statistically significant difference between lorazepam and placebo on all three scales. The ratios for patient improvement were similar to the ratios for percent reduction in mean scores on rating scales. The results of both methods for measuring improvement therefore satisfied the efficacy criteria outlined above.

Global Rating Scale

Intergroup analysis (Kruskal-Wallis test) indicated that lorazepam was significantly more active than placebo at all evaluation periods. Improvement in global severity with lorazepam was significant at 2 and 4 weeks ($p<.05$).

Hamilton Anxiety Rating Scale

Analysis between groups showed that lorazepam was significantly superior to placebo in the following assessments at 2 weeks and the final evaluation: anxious mood, tension, insomnia, genitourinary symptoms, behavior at the interview, psychic cluster, and total Hamilton score. At week 4 lorazepam was significantly superior to placebo in the assessments of anxious mood, psychic cluster, and total Hamilton score. Table 2 presents the scores at pretreatment and at 2 and 4 weeks for key items and clusters of the Hamilton Anxiety Rating Scale; the greater reductions with lorazepam are apparent.

Item Self-Rating Scale

Intergroup analysis (Kruskal-Wallis test) of the ans of clusters, factors, and mean 35-item scores owed significant differences in favor of lorazepam at time periods for somatization, anxiety cluster, and an item score (table 3), and at week 4 and the final aluation for interpersonal sensitivity, anger-hostili- , and general neurotic factor.

fety of Medication

Nine patients reported side effects from medica- n—7 in the lorazepam group and 2 in the placebo oup. In the lorazepam group 4 patients (8.5%) re- rted sedation; 2 (4.3%), psychomotor agitation and itability; 2, nausea; 1 (2.1%), insomia; and 1, urticar-

One of the placebo patients (2.1%) reported psy- omotor agitation and irritability; 1 had urticaria; and eported shortness of breath. Two of the 7 lorazepam tients who reported adverse effects discontinued atment as a result (1 patient had repeated dizziness, rred vision, nausea, and irritability; the other had icaria). The symptoms of the 5 remaining lorazepam tients either disappeared with continued therapy or re controlled with dosage adjustment. In the pla- bo group 1 patient tolerated the symptoms (psycho- tor agitation and shortness of breath), and the oth- , who had urticaria, discontinued treatment.

*p<.01 (Kruskal-Wallis analysis).
**p<.05.

Five patients in the lorazepam group (10.6%) and 11 in the placebo group (22.5%) discontinued treatment. As previously mentioned, 2 patients taking lorazepam discontinued because of adverse effects. The remaining 3 failed to return to continue the study. All 5 of these patients were receiving 3 mg per day at that time. One of the patients in the placebo group discontinued therapy because of adverse effects, and 3 discontinued because of unsatisfactory response to treatment. The remaining 7 dropped out for reasons unrelated to treatment. The dropout rates of the 2 treatment groups did not differ significantly.

Only 6 patients received concomitant medications during the study; 5 of these medications were permitted by protocol (conjugated estrogens, digitalis, norethindrone/mestranol, aspirin, and ethynodiol diacetate/mestranol). One patient received a narcotic-containing mixture, unacceptable by protocol criteria, and was therefore dropped from efficacy evaluation.

DISCUSSION

The superiority of the benzodiazepine class of compounds over its predecessors for the treatment of anxiety is well known. In the present study the relatively small amounts of lorazepam that were used (an average total daily dosage of 3.2 mg on a twice-daily regimen) were much more effective in treating anxiety than the usual doses of earlier benzodiazepines. The need to take medication only twice daily—in the morning and at night—was an obvious convenience to the patients.

The results of this 4-week double-blind study of 95 psychoneurotic patients indicate that lorazepam given twice daily in a mean dose of approximately 3.2 mg per day is significantly more effective than placebo in relieving the great majority of symptoms associated with anxiety. This conclusion is based on intergroup analysis of all 3 rating scales (2 physician-rated and 1 patient-rated scale) at 2 and 4 weeks and the final evaluation. No serious side effects were reported. In addition, there were no adverse interactions between

lorazepam and acceptable concomitant medications including aspirin, digitalis, and hormonal preparations.

Lorazepam is rapidly absorbed and has no psychoactive metabolites. The half-life permits a flexible dosage regimen and rapid attainment of steady-state blood levels, following which there is no accumulation of the active drug (9). Patient acceptability was high with this drug. It appears that lorazepam is an effective, safe, and acceptable antianxiety medication.

Childbirth-Related Psychosis and Familial Symbiotic Conflict

BY RICHARD M. KETAI, M.D., AND MARVIN A. BRANDWIN, PH.D.

The authors present 3 cases of childbirth-related psychosis in young women to illustrate an interpersonal psychodynamic pattern that may contribute to such reactions. In each instance the woman is the submissive partner in a symbiotic relationship with her husband and/or mother. The baby's presence threatens the symbiotic equilibrium of these relationships and leads to the dominant partner's overt or covert aggression against the woman, which precipitates the psychosis. A personal or family history of psychosis may increase the woman's vulnerability to becoming psychotic in this situation.

CHILDBIRTH-RELATED PSYCHOSES are usually considered to be acute manifestations of underlying schizophrenic or manic-depressive illness (1), unique mainly in their temporal association with pregnancy and childbirth. They are similar to psychotic episodes occurring at other times in that biological and psychological p dispositions interact with situational stresses to det mine the specific form and timing of the reaction.

Studies of childbirth-related psychoses have cused on the biological and psychological vulnerab ities of the mother. The pathological effects of stress experienced by the new or expectant father have al received attention. Little consideration has been g en, however, to the role of interpersonal family d namics as a precipitant of these psychoses. The f lowing three case histories of patients recently seen our inpatient unit illustrate a pattern of marital or fa ily interaction that may, we believe, significantly i crease the woman's vulnerability to psychotic rea tion.

CASE REPORTS

Case 1. Ms. A, a 29-year-old graduate student who h been married 5 years, became symptomatic 1 day after t birth of her first child. The night before delivery her husba confessed to having had an affair during the pregnancy. Af delivery Ms. A became agitated, sleepless, aggressively demanding, and suspicious. She accused the nursing and me cal staff of plotting to harm her baby, who she now believ had God-like powers. Her acute disturbance and inability care for her baby necessitated psychiatric hospitalizati Initially a difficult management problem because of aggr sively manipulative manic behavior, she responded well

 0002-953X/79/02/0190/04/$00.45 © 1979 American Psychiatric Association

eatment with chlorpromazine and lithium. The affective na-re of her postpartum psychosis was consistent with a fam- history of mania.

Ms. A and her husband were an intensely symbiotic uple. The marriage was marked by extreme togetherness, reflected in Mr. A's statement, "We spend almost 24 urs a day with each other, including our classes; we have ver been separated." During the hospitalization they mir-red each other's attitudes to an extreme degree, maintain- a hostile united front against the hospital staff. Closer servation, however, revealed a competitiveness tinged th aggression underlying their intense mutual dependency. r. A particularly tended to be critical and demeaning when s own self-esteem was threatened. He remained unable to mprehend that his confession of adultery might have been ensitive. In contrast, during treatment Ms. A commented t she had been deeply hurt by his statement, especially h regard to its timing.

Case 2. Ms. B, a 26-year-old woman in her fifth month of gnancy, was admitted for her third psychiatric hospitali-tion after she became depressed and delusional. After an sode of auditory hallucinations and mild paranoid delu-ns when she was 17, Ms. B functioned adequately until delivery of her first child after 2 years of marriage when was 24. The marriage had been opposed by Ms. B's ther, who had an intrusively close relationship with her ghter and a mutually antagonistic relationship with her n-in-law. The marital interaction was marked by extreme erdependence but marred by increasing arguments during pregnancy.

Three weeks postpartum Ms. B came to the emergency om in an agitated state, believing her baby was controlled the devil. Her husband strongly opposed hospitalization, wing any separation as a threat to the marriage. During ensuing 3 weeks their discord escalated, however, and spite the increasing severity of Ms. B's disturbance Mr. B ted that he was considering leaving the marriage. One ening Ms. B expressed fears of hurting the baby, but her sband left to stay overnight with friends. The next day she pressed the same fears whereupon he left home on an er-d. While he was away she strangled the child and at-mpted suicide by drug overdose. Ms. B's baby died, but survived and was committed to a state hospital where remained for a year. Two months after discharge she came pregnant again by Mr. B.

Despite the similarity of Ms. B's current psychotic symp-ms to those of the previous episode, her husband once in resisted inpatient treatment efforts. Shortly after her nission Mr. B persuaded her to sign out against medical vice, stating that he felt that he would "vanish" without . She became progressively more psychotic and had to be dmitted because of intense suicidal impulses. Throughout ther hospitalization Mr. B opposed the treatment pro-m. Ms. B vacillated between responsiveness to the ward ieu and withdrawal from staff interactions in collusion h her husband's attitudes. However, she responded well nedication and, with concerted staff support, had an un-ntful delivery and postdelivery period.

Case 3. Ms. C was a 21-year-old woman who was admitted eeks postpartum because of an acute psychosis that be- 3 days after delivery. According to her mother, Ms. C been told by her husband in the delivery room that he venereal disease. She then became progressively dis-turbed, showing sleep and eating disturbance, confusion, fear of dying, ideas of reference, and delusional thoughts of her baby being Christ or the devil. This was her second psychiatric hospitalization, the first occurring when she was 17 for what was described in the record as a hysterical psychosis. Ms. C attributed her illness to her struggle "to get away from my mom." Her developmental history provided clear evidence of an intensely ambivalent symbiotic bond with her mother. After discharge she functioned marginally as a "street person" until, despite strong parental disapproval, she married an itinerant rock-and-roll musician who she felt would "rescue" her. Before the marriage, to "prove" her love to him, Ms. C severely stabbed herself in the abdomen. Her parents accused Mr. C of the stabbing, citing the incident as evidence of his being a dangerous person and as justification for their persistent efforts to break up the marriage. Ms. C vacillated between a protective symbiotic involvement with her husband and a more ambivalent symbiotic bond with her mother. During much of the marriage she lived with her parents rather than with her husband, including the final 4 months of pregnancy.

Upon admission Ms. C was agitated, was behaving bizarrely, and was having visual and auditory hallucinations. She expressed fears that her husband would harm her or that he and the baby were in danger. Improvement was gradual and marked by sudden regressive shifts, often precipitated by visits from her mother, who was intrusive and controlling of both the patient and ward staff. Ms. C's mother considered her unfit for motherhood and sought to adopt the baby. She accused her son-in-law of being a danger to her daughter, a concern reflected in the patient's own delusional preoccupations. For therapeutic reasons it was necessary to restrict the mother's visits. In contrast, Mr. C seldom visited, broke scheduled appointments, and became increasingly more difficult for the patient or staff to contact.

DISCUSSION

Pregnancy and childbirth challenge both wife and husband not only with new realistic concerns but with previously unresolved intrapsychic and interpersonal issues rekindled by expectant parenthood. For some this stress may have positive consequences by serving to promote more mature resolutions of conflict. For others the hazards are greater than the available coping resources and regression ensues.

From 2% to 8% of female admissions to psychiatric hospitals are for postpartum illnesses (1). Various psychogenic contributions that have been implicated include the woman's intolerance of the nurturant demands of the child because of her own unfulfilled narcissistic or oral dependency needs, rejection of the mothering role because of inadequate or hostile identification with her mother, reactivation of unconscious psychic conflicts such as oedipal or sibling rivalries, and weakness of personality integration leading to ego identity diffusion in reaction to pregnancy-induced bodily changes (1–3). The pathogenic effects of such psychodynamic factors are compounded by the somatic-physiological changes of pregnancy and her genetic-constitutional predispositions to psychiatric illness.

Studies of men with psychopathologic reactions as-

sociated with new or expectant fatherhood suggest a number of dynamic factors as significant precipitants (4–8). These include increased financial responsibilities, triggering of latent homosexual conflicts by restriction of heterosexual opportunities during the prenatal period, rearousal of unacceptable childhood anger toward parents or siblings, reactivation of unresolved oedipal conflict, and frustration of dependency demands as the wife's attention is diverted to the baby's needs. Towne and Afterman (5) found a characteristic personality trait of chronic, primitive dependency needs among men with psychoses related to parenthood. These men sensed the child as a rival for dependency gratification. Inevitably, their own dependency demands could not be met, and they frequently responded aggressively and destructively toward their wives during and after pregnancy. Even among less disturbed men pregnancy-related stresses may arouse irritability, neglect, belittling, or other forms of aggression. For the psychotically predisposed wife already struggling with motherhood conflicts the husband's abuse or nonsupport may well tip the balance toward psychotic decompensation.

We believe that the presence of a mutual symbiosis with the husband or a parent (usually the mother) increases the woman's vulnerability to postpartum psychosis. The need for symbiotic attachment implies failure of developmental tasks of individuation-separation and establishment of a stable ego identity. These are the core problem areas likely to be stimulated by the psychological and biological pressures of pregnancy.

As the symbiotic relationship may itself be a defense against conflict awareness, the need to resist disruption of a primary defensive structure may provoke an exaggerated reaction to the threat of dissolution of symbiotic homeostasis. This seems applicable to Mr. A and Mr. B. Mr. B's fear that he would "vanish" if separated from his wife reflects his dependence on the symbiotic bond in preserving his own personality integration. In each instance the husband's aggressive behaviors, which were, paradoxically, communication of his need to maintain the prepregnancy marital status, forced the wife into the dilemma of choosing between husband and child. This bind, especially difficult because of the wife's own symbiotic needs and related conflicts, was crucial in precipitating the psychotic reactions in both women, and in one instance proved fatal to the child.

In the third case the main symbiotic bond was between Ms. C and her mother. Ms. C's effort to break this ambivalent attachment by marriage was successfully thwarted by her mother's open and effective resistance, especially when Ms. C became pregnant. The pregnancy was probably perceived by Ms. C's mother as a threat in that it strengthened the husband's position. Her hostility toward Mr. C can also be considered as aggression toward her daughter, who was a pawn in the struggle between her husband and her mother. After childbirth the baby, too, became a pawn. Mr. C's reaction, which expressed both self-protective and hostile motives, was a gradual wit drawal of support from his wife.

All three cases illustrate a common pattern: 1) pre ence of a symbiotic relationship, with the pregna woman as the submissive partner, 2) experience of t pregnancy by the dominant partner as a threat to t symbiotic equilibrium, 3) communication of the pa ner's distress by overt or covert aggression against t woman, and 4) precipitation of a psychotic reaction the woman related to intensification of her own un solved individuation-separation conflicts. In each i stance acute decompensation occurred immediate following an explicit hostile act.

Similar marital dynamics have been observed Martin (9) as potentiating hysterical psychoses times of stress in women with oral-narcissistic, hy terical characters. He relates these reactions to the tachment to the hated but need-satisfying husba when he becomes more destructively unsupporti during family crises. The etiologic role of chron overtly hostile marital interaction in childbirth-relat psychotic reactions of women with primitive, narc sistic personality organization has also been not (10). Specific to our cases is the pseudoharmonious r ture of the marital bond until disrupted by pregnanc The women acknowledged their husband's hostili by direct complaint or in delusional content, or while psychotic. As the psychosis cleared they we resistant to discussion of marital discord, as if attem ing to re-establish the previous protective symbio bond. The symbiotic partner in these cases remain unable to recognize any of his or her contribution the woman's illness.

In this paper we have focused on the role of sy biotic family conflict as a determinant of postpartu psychotic reactions. Consideration of such marital a family dynamics may have significant prophylac value. We recommend that prompt supportive int vention be made when the marital situation shows presence of high-risk circumstances for the pregn woman. Such concern is indicated when the woman involved in an excessively interdependent but cover ambivalent marital relationship, is subject to increas hostile behavior or loss of support from a husband d tressed by the pregnancy, and has a personal or fam history of psychotic illness.

Required Educational Objectives in Community Psychiatry

Y JAMES H. SHORE, M.D., J. DAVID KINZIE, M.D., AND JOSEPH D. BLOOM, M.D.

ommunity psychiatry is an essential requirement of pproved residency training. The authors present a rmat of required educational objectives for this perience. They feel that recent attempts to limit sychiatric consultation to the consultation-liaison odel are restrictive and incomplete. In their view of e psychiatrist's role, community consultation chniques are essential skills for the psychiatric ractitioner.

DEBATE CONTINUES in psychiatric training concerning educational priorities for community psychiatry. This debate has focused on the content of the residency training curriculum, the impact of the community mental health movement on psychiatric practice, and the renewed identity of psychiatrists with the medical model. In a widely quoted article on the educational objectives of a psychiatric residency program, Yager and Pasnau (1) did not mention the inclusion of community psychiatry training. In a recent discussion of psychiatric consultation, Lipowski (2) argues that the preparation of psychiatrists for the consultant role should emphasize a consultation-liaison model instead of community mental health consultation.

The current edition of the *Directory of Accredited Residencies* (3) outlines the essentials of an approved residency:

The curriculum must include sufficient material from the social and behavioral sciences (such as psychology, anthropology, sociology) to help the resident understand the importance of economic, ethnic, social and cultural factors in mental illness. The clinical portion of the curriculum must provide experience in both community and forensic psychiatry. The clinical training in community psychiatry should include experience in a community mental health center such as a school, court, or police department. Training in forensic psychiatry must involve more than solely didactic instruction. It should include supervised clinical experiences such as consultative work with judges, attorneys, police, probation officers, and other professionals in the legal field, and, whenever possible, actual experience in court room testimony.

This requirement is reinforced by criteria developed by the Psychiatric Education Branch at NIMH for evaluating psychiatric residency programs (4). Their guidelines for site visitors encourage the program evaluators to give attention to a balanced curriculum that should include core areas which cover the principles of community mental health and the practice of consultation work.

EDUCATIONAL OBJECTIVES

This report presents the formal educational objectives in community psychiatry that have been developed since 1973 at the University of Oregon Medical School for a community psychiatry training program. Community psychiatry is a half-time, six-month experience in the third postgraduate year, plus a six-month fourth year elective. Each resident must have met the knowledge and skill requirements of the previous two years' educational objectives. Direct patient contact in diagnosis and treatment of major mental illnesses are the precommunity training goals after a medical internship has been completed. The curriculum in community psychiatry includes all activities of indirect services that would be performed by a psychiatrist in a

eceived June 15, 1977; accepted Sept. 2, 1977.

community setting. These involve consultation, interdisciplinary team participation, administration, community educational tasks, supervision of coprofessionals, and forensic psychiatry.

By the end of the resident's rotation in community psychiatry, we expect him or her to be able to perform the following tasks: 1) to enter a community mental health delivery system with a clear understanding of the psychiatrist's role; 2) to negotiate a consultation contract; 3) to work effectively as an interdisciplinary team member in a community mental health program for direct patient services; 4) to work effectively as an interdisciplinary team member in a community mental health program for indirect service or mental health consultation; 5) to conduct a mental health consultation with a community agency; 6) to initiate basic mental health program planning strategies; 7) to work through a process of consultation termination; 8) to evaluate his own role in a community setting with regard to its indirect versus direct service aspects and to demonstrate the use of different models of consultation; and 9) to conduct a precommitment evaluation and court examinations under Oregon's new commitment statute.

By the end of the rotation in community psychiatry, we expect the resident to demonstrate knowledge in the following areas: 1) history of the community mental health movement; 2) basic concepts in social, transcultural psychiatry, and psychiatric epidemiology, including the service delivery system to specific ethnic groups and disadvantaged minorities; 3) general principles of crisis intervention, other types of intervention, and methods of prevention; 4) the role of social, cultural, and family stress in mental health and adaptation; 5) the theory and practice of different models of consultation and the ability to identify the characteristics of direct and indirect service; 6) the structure of community mental health delivery systems in Oregon; and 7) the general principles of forensic psychiatry with particular focus on the Oregon commitment process.

The field experience and the supervision are designed to meet skill objectives. The content of the community psychiatry seminar, designed to meet knowledge objectives, includes the following areas: 1) an introduction to the basic concepts of community psychiatry, historical review, epidemiology, concepts of prevention, and interdisciplinary relationships; 2) the consultation process, describing the models and techniques of community mental health consultation; and 3) specific categories in community psychiatry, program development, program evaluation, administrative psychiatry, and forensic psychiatry.

Evaluation of the educational objectives will be assessed by a formal report both by the community site supervisor and faculty supervisor. In addition, psychiatric residents will be given a mini-Board examination at the end of their third year of community psychiatry rotation, which will include written examination following the ABPN National Board format and a one-hour oral examination. The oral examination will involve two examiners—a psychiatrist and a nonphysician mental health professional. This will evaluate the trainee's ability to apply his knowledge to the implementation of the consultant's role and his understanding of interdisciplinary community mental health issues.

DISCUSSION

Although no set of educational objectives in community psychiatry would be acceptable to all training programs, those we have presented here represent a broad focus that includes principles of public health, the consultation process, the importance of interdisciplinary partnerships, and sociocultural determinants of behavior. The inclusion of forensic psychiatry in the community curriculum seems appropriate since most residency programs will be unable to develop a separate educational program for forensic psychiatry and since most psychiatric activities that involve law take place in community settings.

Oregon's program (5) was planned jointly by the Oregon Mental Health Division and the University of Oregon School of Medicine. The organizational structure reflects an emphasis on state-wide training opportunities throughout the community mental health delivery system. Five distinct groups worked in a collaborative effort to develop a proposal for community psychiatry training. These groups include the Oregon Mental Health Division, Oregon State Hospital, community mental health center directors, and medical school administration, and department of psychiatry faculty of the University of Oregon School of Medicine, and it was felt that a diverse representation of mental health interests would assure state-wide participation, relevant priorities for training placement, and continued community support. More than 40 potential training sites have been developed throughout the state; 24 are located in Oregon's county-state mental health programs, and 5 additional sites are in transcultural settings that involve training in mental health programs for American Indians, Chicanos, or blacks. Senior residents may elect to train in alcohol and drug center mental health education, or in administrative and forensic psychiatry.

Categorical funding from NIMH for postresidency community training (6) is no longer available, and most residency programs must turn to state and county partnerships for appropriate training liaisons. Numerous models of these partnerships have recently been described (7, 8). Fink (9) has described a community psychiatry curriculum in Virginia in association with a single community mental health center and subsequent problems of resident response to the community placement. In Arizona Beigel and associates (10) offer senior residents an opportunity to participate as ex officio community board members. In Massachusetts Sabin and Sharfstein (11) developed a communi

aining program in a psychiatric hospital that had be-ome a community mental health center with responsi-lity for catchment area services.

Psychiatric educators face a special challenge in acing residents in community settings. The identity isis and culture shock (12–14) encountered by many sychiatric residents working in community centers ay reinforce maladaptive habits, a defensive reliance n the medical model, and a negative reaction for par-ipation in any nondirect service community mental alth activity. To facilitate the resident's adjustment Oregon, the program director emphasized clear ructuring of the training situation and continual sistance from supervisors in the conceptualiza-n of the community psychiatrist's role. Supervisors ressed the doctor's unique role as a member of an terdisciplinary health team with a patient-centered cus. Supervision was scheduled weekly with both mmunity program staff and the department's pro-am director. This met the frequent criticism from sidents who in previous community experiences had mplained of poorly structured and inadequately su-rvised training.

Zwerling (15) recently reviewed the impact of the mmunity mental health movement on psychiatric actice and training. He discussed three basic con-pts that will have a profound impact on traditional eory and practice. These concepts must be taken in-account in curriculum design for psychiatric resi-ncy programs—catchment area planning, programs r prevention, and understanding of behavior that in-ıdes multiple sociocultural determinants. However, agree that "one of the formidable problems that es psychiatric education is the need to protect ainst a diffusion of training so that our trainees do t end up learning less and less about more and ore" (15, p. 262). In working toward that goal we ve stressed the psychiatrist's unique role as a physi-an in the interdisciplinary community mental health am.

In our opinion Lipowski's recent attempt to define sychiatric-therapeutic consultation" (consultation consultation-liaison psychiatry) as the primary con-ltation model for psychiatrists (2) is both restrictive d incomplete. We agree that there are two major odels of consultation in the field of psychiatry and at they differ significantly in their goals, participants, ttings, and methods. Lipowski concludes that the sychiatric-therapeutic model of consultation entails ovision of optimal care for the individual patient hile the community mental health model involves provision of assistance to mental health care givers. Community mental health consultation need not exclude, as Lipowski suggested, a patient-centered focus as a primary goal in the working alliance. We believe that both methods of consultation, the in-hospital consultation-liaison model and the community mental health consultation model, are essential skills for the psychiatric practitioner. We propose that both methods should be taught and the psychiatric-therapeutic model be included in another part of our residency curriculum. The Oregon program is designed to give all psychiatric residents a required intensive experience in community psychiatry that will prepare them to meet the pluralistic and changing role of the psychiatric practitioner.

Comparative Efficacy of Tofisopam and Placebo

BY HAROLD L. GOLDBERG, M.D., AND RICHARD J. FINNERTY, PH.D.

Tofisopam is a new agent marketed in Europe as a minor tranquilizer. The authors conducted a 4-week double-blind trial of this drug compared with placebo in 57 outpatients with anxiety and depression. They found that according to physician ratings and patient self-ratings tofisopam was an effective anxiolytic agent for subjects with anxiety and depression. Twenty-one percent of the patients receiving tofisopam and 10% of those receiving placebo reported side effects. The drug was especially effective in the treatment of somatic difficulties.

TOFISOPAM is a new agent developed by a European pharmaceutical firm. It bears a structural resemblance to diazepam (Valium) and oxazepam (Serax). Although clinically a benzodiazepine, tofisopam differs from the diazepam-like minor tranquilizers in the position of the nitrogen atoms (see figure 1). This structural difference manifests itself in a pharmacological and clinical profile that sets it apart from the minor tranquilizers currently in use in the United States.

Tofisopam has been investigated in approximately 1,200 patients in 29 trials in Europe. The European investigators found that tofisopam has the therapeutic characteristics of a minor tranquilizer and also has a mild stimulatory effect. It produced no substantial muscle relaxation, ataxia, loss of concentration, fatigue, or drowsiness. It is currently on the market in France and Hungary.

Szobor's open study of 20 patients (1) found that best results were obtained in vegetative neuroses, depression, and anxiety. According to a 1971 report by Danel in the files of Diamant Laboratories in France, in an open study of 47 patients with anxiety and depression a rapid marked anxiolytic effect was found in 23 patients given a daily dose of 200–300 mg/day of tofisopam. These patients also showed a reduction in psychosomatic complaints. Danel also reported that in an open study by Fouks tofisopam was given to 61 patients for 6 months. The patients who had hyperactivity and anxiety with psychosomatic disturbanc responded particularly well to the drug. Danel also r ported that Herbeuval found that 29 of 41 patients w psychoneurotic disturbances such as anxiety and d fuse neurovegetative symptoms responded favorat in an open study to 100 mg/day of tofisopam in 3 days. Patients with anxiety accompanied by neurov etative symptoms responded best. Finally, Juhasz a Tringer (2) evaluated 32 patients with various forms chronic neuroses and neurotic personality disord given 150 mg/day of tofisopam. Clinical observati using the Symptom Distress Checklist (HSCL) (3) r vealed that patients with somatic symptoms respond best to the drug. Normalization of diminished sex drive occurred in 5 of these 32 patients.

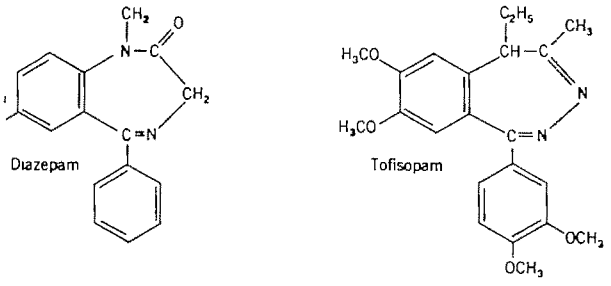
METHOD

Study Design

The study reported here was undertaken to evalu the anxiolytic and antidepressant effects of tofisop and placebo in the treatment of patients with cc current symptoms of anxiety and depression. Subje satisfying the selection criteria were given either r fisopam or a similar-appearing placebo on a doub blind basis. Evaluations were conducted before tre ment and potentially at 1, 2, and 4 weeks after init tion of the study. Subjects could be terminated fr the study for reasons consistent with high standards patient care: lack of therapeutic response and the as ciated need for intervention, emergence of substant side effects, and remission of symptoms. Inform consent was obtained from all of the participating s jects.



Population

A total of 57 outpatients were admitted to the stu All of the patients were at least moderately ill: 42. were moderately ill, 38.6% were moderately sever ill, 15.8% were severely ill, and 3.5% were extrem severely ill. Twenty-one percent of the patients w men and 79% women. The average age was 37 years.

Subjects were admitted to the study if their sco on the depression scale of Raskin and associates and the Covi Rating Scale for Anxiety (5) were grea than 13 and neither score was less than 5. The me total for the depression scale was 9.7, and the anxi mean was 11.2. Subjects were also required to h total Hamilton Anxiety Scale (6) scores greater th

GURE 1
ructure of Diazepam and Tofisopam

. The mean pretreatment Hamilton anxiety total ore was 24.48.

In addition, a depression checklist, patient and fam- history inventory, and the Klein procedure for the agnosis of endogenomorphic depression (7) were mpleted by the physician at intake. Baseline analy- of background characteristics revealed that the ran- mization of the total patient population into the two atment groups clearly produced two patient sam- es that were not distinguishable from each other.

perimental Measures

At each measurement period the treating physician ted each subject on a global scale of severity of ill- ss with seven categories from not ill to extremely verely ill. Measures of therapeutic effect ranged om very much improved to very much worse. Pa- nts rated their experience on a similar scale. Pa- nts who failed to complete the 4-week study were signed a final rating from either the final disposition hedule or the previous rating depending on circum- ances and the opportunity for physician interview.

The Hamilton Rating Scale for Depression (8) was ministered at intake and at week 4 of the study. Un- rtunately, patients who failed to complete the 4 eeks could not be consistently interviewed to obtain al ratings, and posttreatment scores are available ly for completers. The Hamilton Anxiety Scale (6) d Symptom Check List (SCL-56) (3) were adminis- red before treatment and at 1, 2, and 4 weeks on edication. Endpoint ratings were assigned to sub- cts who did not complete the 4 weeks of study. The L-56 was scored to produce the eight composite rat- gs suggested by the assessment manual of NIMH's ew Clinical Drug Evaluation Unit (NCDEU) (9): so- atic complaints, cognitive difficulties, irritability- stility, depression, fear-anxiety, hostility, irritabil- -sensitivity, anxiety.

bject Attrition

Seven patients receiving active medication and 12 acebo recipients were terminated from the study be- e the 4-week completion date. Only 3 subjects owed enough improvement to justify their being ex- sed from treatment.

RESULTS

Twenty-one percent of the patients receiving tofisopam reported the emergence of side effects during drug treatment; 10% of the placebo recipients also indicated some difficulties. The total number of complaints was nearly equal across treatment groups. One patient receiving tofisopam had an immediate and severe emergence of dizziness, syncope, excitement, and confusion that did not moderate after 7 days. This patient was excused from the study. The other patient who dropped out of the study because of side effects had more moderate levels of difficulty, but the side effects (blurred vision and dry mouth) persisted for nearly 2 weeks.

After the first week of treatment no patients had dropped out of the study and no difference was observed between tofisopam and placebo. By week 2 tofisopam was more effective than placebo, but 9 patients had left the study. By week 4, 13 placebo subjects had dropped out of the study. Most of these dropouts were nonresponders, and the week 4 distribution of ratings is greatly influenced by their elimination. The final global illness ratings, not confounded by subject attrition, showed tofisopam to be significantly more effective than placebo (see table 1).

Both the physicians' and the patients' ratings of therapeutic effect were not significantly different for treatment groups (chi-square analysis was used; $p=.05$ was accepted as significant). However, a consideration of the total distribution indicates that if ratings of a little improvement were combined with ratings of nonimprovement, the distributions would be equal to the global illness ratings listed in table 1 and would show tofisopam significantly more effective than placebo.

Analyses of outcome measures rated at each of the time intervals may have been confounded by subject attrition. At week 1 the sample was still complete and the analyses were not biased by the dropout of subjects. At week 2 the subjects with negative responses to tofisopam, as well as some placebo nonresponders, had dropped out of the study, but the ratings at week 2 were definitely biased in favor of tofisopam. By week 4 a large number of placebo recipients had dropped out because of a worsening of illness due to the absence of active medication. Most of the remaining placebo subjects were placebo responders or placebo recipients who had not become sufficiently more ill to warrant intervention. The week 4 data were biased in favor of placebo. Our presentation and discussion of outcome measures will focus on week 1 and endpoint data collections to avoid the confounding of results by sample attrition.

Although an exhaustive analysis of the pretreatment variables revealed no differences between treatment groups, in all of the analyses reported below the posttreatment scores have been adjusted for pretreatment level.

The Hamilton depression scale scores were ob-

TABLE 1
Physicians' Global Illness Ratings*

	Week 1		Week 2		Week 4		Endpoint	
Illness Rating	Tofisopam	Placebo	Tofisopam	Placebo	Tofisopam	Placebo	Tofisopam	Plac
No illness to mildly ill	8	8	17	6	18	9	20	1
Moderately to severely ill	20	21	6	19	4	7	8	1
Total	28	29	23	25	22	16	28	2

*The difference between tofisopam and placebo in the first week was nonsignificant (χ^2=1.0). For the second week it was significant (χ^2=11.96; p<.001). Fo fourth week it was nonsignificant (χ^2=2.94). At endpoint it was significant (χ^2=7.80 p<.01).

tained only before treatment and at week 4. The analyses of these outcome measures involved comparisons of most of the tofisopam subjects (22 of 28) with fewer placebo subjects (16 of 29). The placebo subjects may have comprised a large number of placebo responders. The Hamilton depression total score still showed significantly less illness for tofisopam subjects (analysis of variance covaried for pretreatment ratings; p=.05). The individual items of middle (p<.05) and late (p<.01) insomnia, somatic anxiety (p<.05), general somatic symptoms (p<.05), hypochondriasis (p<.01), and paranoid symptoms (p=.05), although rarely present, were all significantly more relieved for tofisopam subjects. Although the Hamilton depression scale certainly shows significant improvement, this does not necessarily indicate improvement in depression because none of the depression items showed any significant improvement and the reason for significance of the total scale relates to the somatic items listed above. These findings, despite the bias of attrition, suggest that tofisopam may be an unusually effective treatment for patients whose principal conflicts are manifested in somatic concerns.

The Hamilton Anxiety Scale scores were obtained at each rating interval. At the end of week 1 no significant differences were observed between treatment groups according to analysis of variance covaried for pretreatment ratings. The final ratings showed tofisopam significantly more effective in reducing total symptomatology (p<.04) and the cluster of items termed "somatic" (p<.03), which includes insomnia, muscular somatic, sensory somatic, cardiovascular symptoms, respiratory symptoms, gastrointestinal symptoms, genito-urinary symptoms, and automonic symptoms. One other single rating, tension, showed a nonsignificant trend (p=.08) in favor of tofisopam.

The SCL-56 measures are best expressed in terms of the cluster scores. The analysis of these at the end of the first week showed significantly greater improvement for tofisopam on the somatic and anxiety cluster (p=.03 for both) and a trend in favor of tofisopam (p=.06) for the depression and fear-anxiety cluster. The endpoint ratings showed a significant difference (p=.05) in favor of tofisopam on the irritable-sensitive cluster. Four other clusters were nearly statistically significant: somatic (p=.06), depression (p=.07), fear-anxiety (p=.08), and anxiety (p=.09).

The final ratings showed a large number of individual SCL-56 items for which the patients' self-ratings clearly showed more marked response to tofisop than to placebo. Thirteen individual items were sig cantly less prevalent in tofisopam subjects and anot 8 items showed strong tendencies to significa (p<.10).

DISCUSSION

It is clear from the analyses above that tofisop was an effective anxiolytic agent in the treatment these subjects with mixed anxiety and depressi with a unique advantage for patients with som complaints. An analysis of the side effects did not dicate that tofisopam had a high degree of risk for tient safety. The number of patients who dropped of the study because of these side effects (N=2) w somewhat less than expected for an active psych tropic agent. The physician and patient ratings of gl al effect agreed with each other and with the hypot sis that tofisopam is effective. The total Hamilton pression and anxiety rating scale scores show significantly less posttreatment symptomatology tofisopam subjects. The individual Hamilton anxi items indicated that tofisopam was most effective the treatment of somatic difficulties. The patients' s ratings of symptomatology showed significant effe for tofisopam after the first week of treatment, physicians' ratings did not show such rapid impro ment. The self-rating clusters had only one signific difference (irritability-sensitivity), but four ot trends would have achieved statistical significance somewhat larger sample (N=80) with the same dis bution had been analyzed.

Further analyses of the efficacy of tofisopam co benefit from the results of this study. It would be v interesting to see if the interaction between tofisop and a high degree of somatic complaints would cont ue in a larger series and would be distinct from effect of a "standard" medication on patients w anxiety and depression.

:osmetic Surgery as an Antecedent of Life Change

Y MYRON L. BELFER, M.D., JOHN B. MULLIKEN, M.D., AND THOMAS C. COCHRAN, JR., M.D.

f 42 patients who underwent cosmetic surgery, 4 ıtients, who gave no indication of an impending life ıange before surgery, obtained a legal separation or vorce 3–6 months later. These 4 patients had had rong parental domination and hostile relationships ith younger siblings; they had a need for success on eir own terms and for the rapid closure of potential onflict. The authors suggest that such patients are ndergoing significant identity changes that become onscious only after cosmetic surgery, which tests out eir shift from passivity and withdrawal to activity nd participation.

LTHOUGH CERTAIN PATIENTS worry plastic surgeons nd psychiatric consultants because of the possible resence of psychopathology, which could make such n operation inadvisable, most patients seek cosmetic ırgery to alter a feature or features that cause self-onsciousness, unwelcome attention, or adverse com-ent; to gain social acceptance; or to increase their pportunity for employment (1, 2). There is another :oup of patients, however, previously undescribed, who desire a concrete change in their appearance through surgery in preparation for a significant life change. The psychodynamics and psychiatric evaluation of this subset of patients are described in this report.

We studied 42 patients who requested rhinoplasty, abdominoplasty, or augmentation or reduction mammoplasty; each had pre-operative psychiatric evaluations and were followed for 1 to 2 years post-operatively. Within 3 to 6 months after surgery, 4 of the patients obtained a legal separation or divorce without any prior indication that a life change was being planned or evidence of an intervening psychological crisis with an impact on known family dynamics.

These 4 patients present a strikingly uniform psychodynamic pattern. The early life of each was marked by social isolation, hostile relationships with younger siblings, and an early need to opt for security and closure. The patients lacked close parental ties and sought through education to maximize their potential, gain security, and prepare themselves for separation from their families. We did not note any specific patterns of life disruption. These patients' peer relationships were circumscribed and at the time of evaluation for surgery none of them had long-standing friendships of current significance; yet by formal psychiatric criteria none of them would be described as schizoid.

These patients had achieved significant success in their work lives and were currently considered valuable professionally. They did not express the sense of inadequacy described by Meyer and associates (3). Their level of achievement surpassed that of other family members and their spouses.

As for all patients for whom there is concern about their desire for cosmetic surgery, a psychiatric evaluation was performed to determine the patients' ex-

eceived Dec. 19, 1977; revised Feb. 21, 1978; accepted March 16, 978.

he authors wish to thank Joseph E. Murray, M.D., Professor and hief, Division of Plastic and Reconstructive Surgery, Peter Bent righam Hospital and Children's Hospital Medical Center, for his ıpport and review of this paper.

0002-953X/79/02/0199/03/$00.40 © 1979 American Psychiatric Association

pectations about the surgery, the meaning of the expected change in appearance for their personal and social lives, and their spouses' feelings regarding the surgery (3, 4). The requested operations did not have any relationship to a psychologically significant bodily deformity of a parent. In cases where the patients' occupation involved public exposure, we determined whether or not the patients had shared their plans for surgery with their colleagues.

In giving psychiatric clearance for surgery, we used conservative criteria (5), which emphasized a lack of 1) discernible significant psychopathology, 2) unrealistic surgical expectations, and 3) plans for precipitous, unrealistic life changes such as divorce or job change. None of these patients had received psychotherapy or had a history of significant psychopathology.

CASE REPORTS

Case 1. Mr. A, a 37-year-old married management consultant, sought a rhinoplasty at age 35 when he was at a high point in his career. He was referred for pre-operative psychiatric consultation because of the general concern about adult males who request rhinoplasty.

Mr. A was the older of 2 male children, and his early life had been marked by parental unavailability and lack of affective interchange. He saw his father as an angry, unloving, aggressive person who was dominated by his wife. He saw his mother as a passive-aggressive woman. As far back as he could remember Mr. A recalled feeling a sense of distance from his parents, a persistent desire to "escape," and a fear of parental retaliation. He had had few outside interests other than his studies, few friends, and did not date until college. Mr. A received a doctorate degree in physics but to achieve financial success chose a career in management, where he was successful. He married the first woman he dated, a woman who made few demands and who by virtue of her training could be financially independent. Retrospectively, Mr. A saw his marriage as a calculated decision, made at the right time with the right person, and one that caused the least disruption with his family.

Mr. A had a significant objective nasal deformity but a more obvious divergent strabismus. He said that at that point in his life he was feeling better about himself, generally took more pride in himself, and wanted a rhinoplasty to achieve a more pleasing profile. He had previously lost 13.6 kg through diet and exercise and had begun to dress fashionably. There was no evidence of overt marital discord, but Mr. A said that his wife "lacked the vision of the future" which he had achieved as he became successful.

Postoperatively Mr. A expressed immediate satisfaction with his rhinoplasty. Two months later he called the psychiatric consultant for an appointment and said that he was considering a separation from his wife. There had not been any intervening psychological crisis. The response to the rhinoplasty at work, socially, and within his family had been entirely satisfactory; the patient, however, felt that now his wife would be unable to match his lifestyle, and when he confronted her with changes that he wished she would make, she refused, which led to their eventual separation.

Case 2. Ms. B, a 24-year-old married dental hygienist, had had an augmentation mammoplasty when she was 22 and a year later requested a cosmetic rhinoplasty. Psychiatric consultation was sought because of the minimal objective deformity and the fact that this was the second request for plastic surgery within a year.

Ms. B was the oldest of 4 girls. In her early life emphasis had been placed on family and loving one's own family, yet Ms. B recalled a lack of affective contact and much covert communication among family members. Her family considered the role of the woman to be stereotypically passive and compliant.

Ms. B met her husband in grammar school and married him to be with him while he was in the service. Over the following 6 years Ms. B received an associate degree and became a dental hygienist. In this job, and because she was in a metropolitan area, she found herself exposed to a wider variety of people and experiences than previously. She found her husband resistant to these new experiences, and increasing tension developed. Ms. B resolved to correct what she felt to be inadequacies in her self-image, ostensibly for her own sense of well-being.

Six months after a successful minimal rhinoplasty Ms. B contacted the consulting psychiatrist to say that she was separating from her husband. She placed emphasis on her failure to get her husband to change. She described him as resistant to change, distant, and uncommunicative. Ms. B said she wanted the opportunity to explore interests and social contacts that her lifestyle with her husband had not permitted.

DISCUSSION

The 4 patients in the study group evidenced strong parental domination, a need to succeed on their own terms, and a need for rapid closure of potentially conflictual situations. Diagnostically, such patients may be seen as having significant concerns with their identity that only come to consciousness and lead to life changes after cosmetic surgery. The operation serves as the fulfillment of some seemingly less significant goal, i.e., changing an aspect of their body, but, as discussed by Reich (1), the initial reason a patient requests cosmetic surgery may not be the true reason he or she fears that the operation may be refused, and it has been noted that the real, less conscious motivation may become evident only after surgery. Meyer and associates (3) elaborated on the same patients' wish to shift from passivity and withdrawal to activity and participation, which is signified by the surgical intervention.

The cosmetic surgical procedure in these cases can be seen as a manipulation, performed unknowingly by the surgeon, which serves to consolidate the patient's identity and test out, in a derivative manner, the patient's acceptability and competence in an active role. The patients were pleased with their surgical outcome and less consciously saw this as permission to pursue active change in other spheres of their lives, namely separation or divorce. The psychiatric consultant should be alert to the possibility of marital disruption when a patient requests cosmetic surgery and his or her history includes difficulty with affective expression, a marked difference in the level of achieve

nt from that of his or her spouse, a need for closure, d the sense that the patient is asking the surgeon to odify his or her appearance in conjunction with a ent professional, personal, or social success.

The consultant seeing such patients must pursue the ective gaps in these patients, inquire carefully into possibility that the requested surgical operation resents a displaced concern (6), and assess the de- e to which surgery offers the patients the opportu- y to escape their passivity. Psychotherapy may per- the exploration of the less conscious motivations ding up to cosmetic surgery and permit the decision make a life change to take place more openly.

he Impact of Political Process on Hospital Psychiatry

GEORGE L. HOGBEN, M.D., TECLA CRITELLI, M.D., AND RALPH HOFFMAN, M.D.

litical forces motivated the New York State partment of Health to withhold payment for dicaid-financed inpatients on therapeutic passes. e elimination of therapeutic passes had many gative effects on patient care. The authors believe s experience demonstrates that political factors can erwhelm standard clinical practice and reasoned alth planning to force irrational change on health e delivery.

LITICAL EVENTS HAVE produced remarkable anges in psychiatry. Altered attitudes on the part of alth authorities have led to dramatic reductions in federal budget for training psychiatrists. Economic tagflation" has contributed to shorter hospitalizations for many patients with acute psychiatric conditions. Prolonged hospitalization for chronic disorders has been much less available since passage of the Community Mental Health Centers Act of 1963. Funding for psychiatric research has been drastically curtailed by these economic conditions.

Many professionals believe these political processes are adversely affecting psychiatric patient care. However, data establishing a negative impact of political events on patient care have not been forthcoming. In fact, benefits from short-term versus long-term hospitalization have been demonstrated (1). These results suggest that political forces which reduce the amount of time available for inpatient therapy may benefit some patients.

However, there are many aspects of patient care that have been adversely affected by political forces. For example, psychiatrists have relied on therapeutic passes (temporary authorized absences from the hospital) in treating hospitalized patients. Most therapeutic passes are granted for short periods during the day. Recently, New York State health officials denied reimbursement to hospitals for time spent on therapeutic passes by Medicaid-financed patients. Many hospitals eliminated therapeutic passes in response to this directive. This paper outlines the political process that led to the Medicaid reimbursement guidelines and describes the impact on the patients and staff in a short-term psychiatric unit of the elimination of therapeutic passes.

POLITICAL PROCESS

Our description of the political process that led to the decision to end reimbursement to Medicaid patients on passes is based on reports that appeared in the *New York Times* in October and November of 1976.

After it came close to bankruptcy, New York City was forced to adopt austerity measures to satisfy its fiscal rescuers, New York State and several large monetary institutions. A projected budget deficit of $100 million in the Health and Hospitals Corporation threatened the success of the austerity program. The root of the problem seemed to be 5,000 unused beds in the municipal, voluntary, and private hospital system (2).

The situation was highly sensitive because many different people, state and city agencies, and jobs were involved. The Health and Hospitals Corporation had already effected major cutbacks in its own system and did not favor additional measures. The voluntary and private sector was also reluctant to reduce bed capacity.

Political maneuvering over the budget between the mayor of New York City and the governor of New York State sifted down through the network of city and state agencies that have overlapping responsibilities. The State Department of Health and the Bureau of Audit and Control both criticized the city's inability to check Medicaid abuses (2, 3). The City Department of Health and the Human Resources Administration countered by charging that the state agencies had not cooperated by tightening regulations.

On Oct. 28, 1976, the *Times* reported that state auditors had uncovered city procedures to fill beds with Medicaid patients in an effort to reduce deficits (4). State officials warned that Medicaid would not pay for unnecessary hospitalizations.

On Nov. 9, 1976, the *Times* reported that state auditors had "discovered" the practice of therapeutic passes for psychiatric patients (5). The state agencies said they intended to review the granting of therapeutic passes. Over the next five weeks the state agencies quietly designed a policy to deny hospitals reimbursement for Medicaid-financed patients during the time they were on therapeutic passes. The policy was based on the definitions of an inpatient in the Code of Federal Regulations (6) and the State Medical Handbook (7), which govern the administration of medical assistance programs. These administrative codes define an inpatient as one who receives room, board, and professional services in a hospital on a "continuous 24 hour basis." Hospital Memorandum 76-128 (8) from the New York State Department of Health instructed hospitals "not to bill Medicaid for periods while patients are not actually in the hospital." The memorandum threatened that hospitals violating the directive would be referred to the Attorney General for fraud investigation.

Hospital administrators were informed of the new policy in mid-December 1976. The unit chiefs of Mount Sinai Hospital were notified of the policy a instructed to implement it as soon as possible. The p icy was implemented by the unit we will describe Jan. 1, 1977.[1]

SETTING

From Jan. 1 to March 30, 1977, the 3 months af the termination of therapeutic passes, observations individual patients' courses of hospitalization a changes in the milieu and staff responsibilities were corded. These observations were made during co munity and small-group meetings, therapeutic team ports, and staff meetings.

The 23-bed general psychiatry unit is one of f adult and child inpatient psychiatry units at Mo Sinai Hospital. During the 3-month observation per 65 patients were cared for on the unit. Forty-four tients were service cases, 21 of which were financ by Medicaid. Nine service patients had no insura coverage on admission but qualified for emerger Medicaid support. Fourteen service patients had B Cross or Medicare insurance. Twenty-one cases w semi-private patients, financed by Blue Cross or Me care. Therefore, the care of 46% of these patients v directly affected by the stoppage of therapeutic pas for Medicaid patients.

OBSERVATIONS

Patient and Staff Reactions to Policy

The policy of discontinuing therapeutic passes Medicaid-financed patients was announced at a regu community meeting. The patients were shock Many therapeutic meetings during the observation riod were devoted almost exclusively to the patier futility and rage at the loss of therapeutic passes. tients rejected attempts to introduce topics relatec other important therapeutic issues. They thought authorities did not care about patients with me conditions and openly wondered if mental health pl ners realized the needs of psychiatric patients. The tients believed the action showed "again" that gove ment was unresponsive to citizen needs. They w convinced that politics rather than therapeutic n governed care.

The staff was also shocked and angry at losin valuable therapeutic tool. Fostering independenc an overriding treatment goal of the unit. Short pas were used to achieve clearly defined therapeutic go Moreover, everyone felt powerless because there been no warning about the new pass procedure contingency planning was therefore not possible. M rale fell sharply and staff acted with grim resignatior

The patients thought that the loss of therape

[1]The policy was rescinded in November 1977 and Medicaid-finar patients may now have short therapeutic passes.

sses would increase their reliance on the hospital. any patients felt hopeless about leaving under these rcumstances. Chronic patients who had experienced evious separation from the hospital were panicked at e prospect of leaving "cold turkey." One patient ted, "I had so much trouble getting out of here last ne even in small steps. I don't think I'll ever get out w."

These discussions stimulated the patients to draft a tition to Medicaid officials that explained the probms created by the termination of passes and requested the decision be reversed. The petition, which scribed the patients' fears about increasing dependcy on the hospital, was circulated throughout the spital and all members of the hospital community re asked to sign it.

fects of Policy on Patients' Hospital Course and anagement

The patients' dependency concerns were well-unded. Many of them had no place to live after disarge and no job or money. Other patients had serely strained relationships with roommates and fam- members. Therapeutic passes had given patients ne to conduct job interviews, make basic living arngements, and test themselves in difficult interrsonal situations before discharge. Without these portunities, patients were severely handicapped in eparing to leave the hospital. For example, a 56-ar-old man who led a withdrawn life had abandoned s single room and earthly possessions during an epide of involutional psychosis. When the psychosis reitted, he was unable to leave the unit to make new ing arrangements and buy basic necessities. He beme a frightened, depressed, and actively contemated suicide, saying, "I'd rather kill myself than do this after I leave."

This reaction was typical of the difficulties expericed by the patients denied therapeutic passes. Most tients confronting abrupt discharge without graded paration experiences developed severe panic attacks their discharge dates approached. These patients came restless and irritable and exhibited insomnia, lpitations, and breathlessness. Several patients exrienced severe reactivation of their psychotic sympms, which delayed their discharge. Many patients, en those who had not had suicidal ideas on admison, actively contemplated suicide. These suicidal eoccupations reached epidemic proportions on two casions.

The staff attempted to conduct accompanied walks d home visits to help patients with separation fears. alks had always been offered to disorganized pants to afford some time away from the unit routine. ey were now used with organized patients to prode some predischarge independence. The walks re very stressful to the staff because this added reonsibility had not been considered in staffing plans. rsonnel cutbacks had also reduced the number of aff available for patient care. The accompanied walks and home visits further removed staff from important work on the unit.

Many patients were angry and resentful over being accompanied off the unit when they felt well. They thought that staff was suspicious about their mental condition. In some instances patients became convinced they were not progressing and doubted their own status. One patient remarked, "I feel all right now but I don't know what to think when I can't go out alone. I begin to think I'm a baby and doubt my own competence."

Effects of Policy on Interpersonal Relationships

As the patients directly experienced the impact of the decision, they became more angry and resentful toward the hospital and unit staff, especially the doctors. The patients felt the hospital administrators and doctors should have prevented government officials from making the policy. They were dismayed at seeing the doctors as helpless as they themselves were in directing therapeutic plans and repeatedly urged the staff to ignore the ruling. When pass requests were denied, patients charged that the staff was not dedicated to helping them meet the realistic problems of their lives. One woman angrily commented, "None of you care whether I can handle how I feel toward my husband. If you did you would let me out to see if I can. These family meetings aren't the same as living with someone."

The splitting of patients' anger among Medicaid authorities, hospital administrators, and unit staff created a difficult problem for social therapy on the unit. Patients frequently tried to make staff responsible for solving their problems with interpersonal relationships and daily living. Since patient independence is a unit goal, staff members were often objects of patient anger. Staff was competent in helping patients identify anger and handle it through verbalization and mobilization of personal resources. However, the staff felt therapeutically helpless when the patients expressed anger at them over the pass situation. The staff was powerless, and no solution seemed available to promote patients' personal independence. The staff could not catalyze the patients' problem-solving abilities, and pointing out the reality of the process leading to the pass policy only ignited more patient anger. The patients felt the staff had lost its credibility. The patients' resentment of staff spread to other therapeutic endeavors and anger and mistrust were pervasive. The patients and staff became divided.

The division between patients and staff was extremely frustrating because the pass policy created many therapeutic and interpersonal tensions that demanded candid communication. Patients with separation fears and suicidal preoccupations were of great concern to the staff. Moreover, patients felt cooped up and overstimulated by the close personal contact on the unit, and tempers often flared between patients. Several patients with paranoid tendencies who relied on periods of isolation overtly threatened bodily harm

when they could not leave the unit for short periods. Patients felt sexually stimulated by close conditions and expressed sexual feelings for other patients and staff during open meetings for the first time in our experience. The patients also decided they could work around pass restrictions by eloping, and several patients eloped to test this idea.

The patient community was also divided between those who could and could not have passes. Even though all of the patients denounced the situation, Medicaid patients openly expressed jealousy and anger toward patients who were receiving passes. Many patients said the situation was similar to what they had experienced all their lives. "The rich get richer." Medicaid patients frequently said they always felt like second-class citizens. Being treated differently from others on the ward reinforced their sense of inadequacy, a feeling that "I always knew others thought I was no good. Now I know it . . . I'm not."

COMMENT

This experience shows how political factors can overwhelm time-honored clinical practice and health planning activities to force irrational change on health systems. Politicians and bureaucratic agencies actively competed to uncover fiscal waste and find immediate solutions. It is logical not to charge Medicaid when a patient does not occupy a bed. However, a therapeutic pass is not an absence from in-hospital status. An interpretation permitting passes could have been made within the Medicaid regulations. Medical consultation was not sought during the process of changing the pass policy. Medical input should be a part of the decision process in order to avoid formulating policies opposed to clinical practice. Procedures to study the clinical and economic effects of the new policies were not established. Political process was the only means available to report the effects of the pass policy on patient care.

The termination of therapeutic passes had disastrous effects on patient care. Most patients who had been denied therapeutic passes developed severe panic reactions and active suicidal ideation during the discharge process. Symptom development at discharge is a known phenomenon, but the number of patients affected and the extent of their reactions increased greatly after passes were eliminated. Interpersonal tension, common on inpatient units, rose to dangerous levels. The pass restrictions reinforced the patient's low self-esteem. Patients overtly mistrusted staff over the pass issue, which made the development of positive therapeutic relationships extremely difficult.

The role of the staff was dramatically altered by the pass restrictions. Valuable staff time was diverted from intervention in the problems that brought patients to the hospital. Therapeutic meetings were largely devoted to discussing the patients' reactions to the loss of therapeutic passes, the predischarge panic and suicidal preoccupations, and increased interpersonal tensions.

Ironically, the change in pass policy, established to reduce costs, may have increased the cost of patient care. Depriving patients of graded separation experiences might lead to inadequate adjustment in the community and to increased likelihood of relapse, thereby increasing the number of hospitalizations. Moreover, so much time was drained from the unit's primary mission that patients may not have been adequately diagnosed.

Political events have a profound impact on mental health and psychiatry. The political process described herein occurred in a crisis atmosphere that suppressed open discussions. No provisions were made for planned implementation of the new policy or for assessment of outcome. In this case the political process was destructive to the patients, their care, the staff and possibly even the precipitating economic conditions. Open political processes, planned policy implementation, and well-organized assessment procedures are urgently needed to prevent destructive consequences of political action.

ir Pollutants and the Admission Rate of Psychiatric Patients

Y MEIR STRAHILEVITZ, M.D., AHARONA STRAHILEVITZ, M.D., AND JOHN E. MILLER, M.A.

ie authors studied the correlation between mean ily levels of several air pollutants and the number of ergency room visits and inpatient admissions to a ychiatric hospital in St. Louis during one summer d fall. Nitrogen dioxide and carbon monoxide owed a positive correlation with emergency room sits by all patients, and nitrogen dioxide also had a sitive correlation with inpatient admissions of bjects with diagnoses that were unknown or could t be specified as psychotic. Nitrogen monoxide owed a negative correlation with inpatient dmissions during working days (but not during ekends and holidays) for all patients, as well as for ose with diagnoses that were unknown or could not specified as psychotic.

HE EFFECT OF air pollution on a variety of medical nesses has been studied extensively, and it is a well-tablished fact that certain air pollutants have a delerious effect on several medical illnesses (1). How-er, little is known about the effect of air pollution on sychiatric illness. In the present study, we examined e correlation between the mean daily levels of sever-air pollutants and the daily number of emergency om visits and inpatient admissions to Malcolm Bliss ental Health Center, a psychiatric hospital serving e population of St. Louis.

ETHOD

The study period consisted of 149 days during the mmer and fall of 1972. The air pollutants studied in-uded coefficient of haze, total oxidants, total hydrocarbons, carbon monoxide (CO), nitrogen oxide (NO), nitrogen dioxide (NO_2), and sulfur dioxide (SO_2). Total oxidants, CO, NO, NO_2, and SO_2 were measured in parts per million by volume. Total hydrocarbons were measured in methane equivalent parts per million. Coefficient of haze was measured by units of coefficient of haze per thousand lineal feet. The air pollutants were monitored in three stations in different areas of the city. The mean daily pollutant levels for the three stations were computed.

The Pearson correlation coefficient was computed between the mean daily level of each pollutant and the daily number of emergency room visits and inpatient admissions. Correlations with the daily number of emergency room visits were computed for the total patient population but not according to diagnosis, since no diagnostic information was available on patients who came to the emergency room but were not admitted to the inpatient service. Correlations between pollution variables and the number of inpatient admissions were computed for the total patient population as well as for selected diagnostic groups and specific diagnoses. The following diagnostic groups were used: psychotic illness (such as schizophrenia and major affective disorders), nonpsychotic illness (such as neurosis and personality disorders), and diagnosis either unknown or cannot be specified as psychotic (such as alcoholism, organic brain syndrome not specified as psychotic, and undiagnosed psychiatric illness).

Air pollution variables were correlated separately with the number of inpatient admissions for the following specific diagnoses: organic brain syndrome, schizophrenia, major affective disorder, neurosis, transitional situational disturbance, behavior disorder of childhood or adolescence, personality disorder, and alcoholism. The diagnosis used was the discharge diagnosis recorded in the medical record at the time of discharge. The diagnosis was made by at least one experienced staff psychiatrist.

Since we computed the correlation of seven air pollution variables with the number of emergency room visits and inpatient admissions, we choose an α level of .005 as statistically significant. Alpha levels of .01 and .05 were considered borderline significant. Pearson correlation coefficients were computed for the following periods: all days (N=149), days on (e.g., all days excluding weekends and holidays) (N=94), and days off (e.g., weekends and holidays) (N=55).[1]

Box 1502, Galveston, Tex. 77550.

e authors would like to thank Mr. W.L. Hagar of the St. Louis vision of Air Pollution Control for providing the air pollution data.

[1] For total hydrocarbons all days=73, days on=48, and days off=25.

0002-953X/79/02/0205/03/$00.40 © 1979 American Psychiatric Association

The reason for computing correlation coefficients separately for days on and days off was related to the following considerations.

1. The hospital was understaffed, particularly with physicians during days off. This was likely to influence the admitting physician's decision concerning admission of patients.
2. Pollution levels were likely to vary between days on and days off. Less pollution was generally expected on days off because of decreased industrial plant operations and decreased traffic.
3. Patients' exposure to air pollution could vary between days on and days off. On days off part of the patient population, such as laborers working outdoors on days on, might protect themselves to some extent from the effects of air pollution by remaining indoors.
4. The probability that patients would go to the emergency room, and therefore the probability that they would be admitted, might also vary from days on to days off.

In addition to the simple correlation coefficient we also used the first-order partial correlation coefficient, which indexes the relationship between two variables while controlling for the effect of a third variable. The partial correlation used in this study controlled for the days on/days off effect. The existence of nonzero partial correlations would indicate that there are relationships between air pollution variables and behavioral variables that are independent of the days on/days off effect.

RESULTS

The coefficient of haze, total oxidants, total hydrocarbons, and SO_2 did not show any statistically significant correlations with emergency room visits or inpatient admissions. Mean daily CO concentrations showed a significant positive correlation with daily emergency room visits for all patients during all days ($N=149$, $r=.25$, $p<.005$) and with daily inpatient admissions during all days for the group of patients with diagnoses that were unknown or could not be specified as psychotic.

NO_2 correlated positively but not significantly with admissions for all days for alcoholics ($r=.22$, $p<.01$). NO_2 also showed a simple correlation with admissions for all days as well as a partial correlation with patients with organic brain syndrome ($r=.20$, $p<.05$ and $r=.18$, $p<.05$, respectively).

Mean daily NO correlated negatively with the daily number of inpatient admissions for all patients on days on ($r=.36$, $p<.005$). NO correlated negatively with daily admission rates for patients with diagnoses that were unknown or could not be specified as psychotic on days on ($r=-.33$, $p<.005$). The partial correlation for this group of patients was also significant ($r=-.25$, $p<.005$). In specific diagnostic groups, the mean daily concentration of NO correlated negatively but not significantly with days on admissions in alcoholics ($r=-.26$, $p<.05$) and in patients with organ syndrome ($r=-.21$, $p<.05$).[2]

DISCUSSION

Our findings suggest that concentrations of pollutants may be correlated with the emerger visit and inpatient admission rates of psychi tients. Such correlations are apparently r strong ones. Even though our selection of cance level of .005 was based on reasonable erations, it was still to a certain extent arbitr important to stress that any research strategy multiple analyses may lead to spurious "sig results.

The number of patients in some of our d subgroups might have been too small to test fo cant correlation with the level of air pollutant dition, one has to keep in mind that even if th a valid significant correlation between a vari specific air pollutants, such a correlation woul course, indicate a causal relationship; it might reflect a correlation between the patient "beh variable and another set of environmental that are correlated with the pollution variable ed in our study. Keeping all of the above rese in mind, it appears to us that our data suggest tentative hypotheses.

It appears from our data that certain ps conditions may be sensitive to specific air po mean daily air concentrations of NO_2 may be ly correlated with the number of emergency r its by all patients and with the number of inpa missions of persons with diagnoses that are n or cannot be specified as psychotic.

It is possible that patients with diagnoses of ism and organic brain syndrome are particular tive to the level of NO_2 in the air, since th groups showed correlations that approached cance. Both the combined sample of patients subgroups with a positive correlation betwe levels and inpatient admissions showed a nega relation between the daily number of inpatien sions and air concentration of NO. These obse may reflect a negative correlation between a tion levels of NO_2 and NO, or they may refle tective effect of NO on the "irritating" effec on some psychiatric patients. The protective e NO on the damaging biological effects of known (2). NO is a known anesthetic and also algesic qualities (3). Thus the possibility tha have a beneficial effect on certain psychiatric deserves consideration.

The negative correlation between NO level patient admissions only on days on may be r the existence of threshold phenomena for the

[2]A table summarizing the results is available from Dr. M levitz on request.

ect of NO_2 on some psychiatric patients, with a protective effect of NO being apparent only when the level of NO_2 exceeds this threshold level. The concentration of NO_2 in the air might have been related to increased industrial plant activity during days on compared with days off.

Air concentrations of NO_2 and NO were rather low. The maximum mean daily levels measured in our study were .29 ppm for NO_2 and .97 ppm for NO. The minimum level of NO_2 known to cause biological effects in acute exposure experiments is about 13 ppm (1). Thus if our findings on the correlation of NO_2 and NO with emergency room visits and inpatient admission rates indeed reflect a valid causal association, these findings may indicate that certain psychiatric patients are unusually sensitive to the effects of NO_2 and NO.

Our findings also indicate that mean levels of CO in the air may be associated with increased emergency room visits by psychiatric patients. The maximum air concentration of CO that was recorded in our study was 23 ppm, which approaches the minimum level of 30 ppm known to cause biological effects in man in acute exposure experiments (1).

Our data suggest that it may be worthwhile to evaluate the possibility of a therapeutic effect of low levels of NO on certain psychiatric illnesses, in particular alcoholism and organic brain syndrome.

INDIVIDUALS BEGINNING psychiatric training usually have primarily scientific backgrounds. The difficulty of gaining acceptance to medical school encourages interested undergraduates to specialize early in sciences in hopes of furthering their chances, and medical school intensifies the scientific focus. Yet every physician needs exposure to the humanities as well, and as Nemiah (1) notes, the psychiatrist especially must be both poet and scientist. Chessick (2) summarized it well when he stated,

> The urgency for training future psychotherapists in the humanities and immersing them in the arts as well as the usual scientific subjects has a theoretical foundation. The psychotherapist, to do an optimal job, must be familiar both with the language of scientific understanding and of the humanistic imagination and he must be able to shift back and forth with facility between these maps of psychic interaction so that what he misses on one map, he finds on the other. (p. 334)

In an effort to further develop residents' humanism and capacity for empathic understanding, a number of medical schools have made use of a seminar in which major literary works are discussed. Since 1958, Bar-

0002-953X/79/02/0207/04/$00.45 © 1979 American Psychiatric Association

chilon has been using such a seminar in the education of psychiatrists and medical students (3). Hofling (4), Fellner (5), and Silberger (6) have reported on variations in the literature seminar format. Psychiatrists since Freud have written at length on the nature and function of art, examining the creative process and product from every conceivable vantage point. Several recent publications dealing with the psychology of esthetics are especially relevant to the use of great literature in psychiatric education (7–11). In contrast, the psychiatric literature on films is much less extensive. Munsterberg in 1916 (12) and Montani in 1938 (13) made early contributions to the esthetics of the cinema. Increasingly, psychiatrists are exploring commercial films and the work of individual filmmakers, reviewing them in depth from a number of perspectives (14–20). Schneider recently traced the history of movies' depiction of psychiatry and psychological themes (21). Didactic and documentary possibilities of film have long been recognized; the literature reflects psychiatry's and other health sciences' extensive experience with such films as audiovisual aids to education (22–27). However, reports of cinematic art being utilized in the training of psychiatrists or other mental health professionals are lacking.

Film has several advantages over literature as the artistic medium around which to build a teaching seminar. Of all the art forms, the motion picture seems to have the most direct access to the unconscious. Primary process thought utilizes visual images extensively, and part of the difficulty in adequately communicating primary process material stems from how poorly it lends itself to literary verbal language. Attempts to convey primary process in the vehicle of secondary process inevitably compromises the individuality and richness of the former even after it is retranslated into mental images in the mind of the receiver. Montani and Pietranera (13) noted that if it were possible "to transmit images from brain to brain, very often films would pass from man to man, and if the motion picture machine were so simple as the pen or as spontaneous as speaking, such would undoubtably occur." Insofar as psychotherapy entails frequent shifting between primary and secondary process thought, the viewing of films exercises that therapeutic skill.

In their nonverbal, visual imagery movies are closely related to dreams. Both utilize ambiguous images that are over-determined and multilayered in their function. To accomplish this, both movies and dreams employ the mechanisms of condensation and displacement. Film montage ignores the rules of time, size, and association to connect seemingly unrelated images; concrete similarities such as position and color express abstractions. Specific dream sequences in films, as exemplified in Bergman's *Face to Face,* as well as montage footage that is dream-like, as in Fellini's *Juliet of the Spirits,* have practical utility for the psychiatrist who seeks to help his patients through an understanding of their dreams.

Contemporary movies are technically far advanced compared with the early silent films. Today's directc have at their disposal almost unlimited technology well as actors and actresses who are artists in th own right. An increasing number of superbly talent artists are drawn to film as their medium because of tremendous potential. To think of film as art is no lo er to be restricted to the stereotype of a foreign f with subtitles shown in a small theatre where coffe served in the lobby. Pakula, Altman, and Kubrick, name a few of the growing number of creative and s cessful American filmmakers, have joined Bergm Truffaut, and Fellini in contributing serious works major consequence. Thus advances in cinematograp have led to an enlarged and varied pool of films fr which those interested in the art can draw. These sa advances are responsible for the uniquely mu sensory nature of most contemporary films. Tc screenplay that is often a significant literary achie ment on its own, auditory and visual elements are a ed. The rape scene in Kubrick's *Clockwork Oran* for example, is at once visually horrifying and m dane; the association of "Singing in the Rain" with violence emphasizes the tension arising from confl ing emotions. Contemporary cinema entails the pr essing of verbal, visual, and auditory input to tota experience the work. Intense concentration must complemented by flexible receptivity, and intellect awareness combined with emotional sensitivity, if c is to fully appreciate a film. Effective psychotherapy evaluation demands much the same process.

A final advantage of the cinema as the focus o seminar on psychodynamics in art has to do with pr ticality. The busiest resident can still find time to se film that will be discussed, when the task of readin novel would be impossible. Viewing a film, like re ing, is an individual experience, but a night at the m ies can be surrounded by social activities. The ne ness and rapidly changing nature of the cinema ma for few "experts" who can inhibit discussion or t the seminar into a passive learning experience. W films as with novels, many are made for profit or exploitation and have little artistic merit; fortunat the trend toward reruns of great films helps ensur regular supply of challenging works over time.

COURSE DESCRIPTION

Experience with a film seminar as part of the psyc atric residency curriculum in two area training p grams over the past five years has led to the exist format, which seems to best promote general c cussion and deep involvement with the films. The se inar is elective for residents in all three years of tra ing. Spouses and friends are included, which helps involve them first-hand in the training experience a also balances the traditional male perspective in p chiatry.

Several faculty members with whom the reside have sufficient contact to feel relaxed and familiar a attend. Meetings are held at the home of different p

cipants each time, and socializing over wine and nacks precedes the discussion. The seminar group sually meets monthly, the exact frequency being dermined by what films are running at the area eatres. Only one criterion is used to determine the itability of a given film for the seminar: it must sufficiently excite at least one member of the group that he she recommends it. Using this method, in combination with growing sophistication, has led to a series of vely discussions; mediocre experiences are rare. Frequently someone who was unimpressed by a film aves the seminar with an entirely different feeling, as e discussion provides new perspectives and insights. rongly negative reactions contribute greatly to the ow of the discussion and often to individual growth d self-awareness.

Early in the life of the seminar several facilitating chniques were used to stimulate or direct discussion. hese included 1) a series of questions prepared by the ader designed to relate details to the film as a whole, a short presentation by one member of his analysis the film, or 3) provocative reviews by major film itics. With time, however, group cohesiveness and embers' heightened appreciation of the film medium ade these techniques less crucial. Now penetrating estions arise within the group, and members are eager to contribute their own perceptions and analyses. terestingly, the familiarity and sophistication seem be group functions that are readily transmitted to ch year's incoming residents. It also became apparent that films are difficult to appreciate in detail because of their fast pace and multisensory input. Thus me participants see films two or three times before scussing them, perceiving new aspects with each ewing. A penlight and notepad are also useful during movie for recording impressions or questions. Reading the novel or even the screenplay is interesting for ntrast, but experience has underlined the obvious: e filmmaker's creation is unique and personal, and a eat film stands alone no matter how it is related to its urces.

In describing the literature seminar, Silberger (6) has dvocated limiting discussion to the psychology of individual characters for simplicity and thoroughness. ecognizing the difficulties involved in a broader ope, we have nonetheless found it useful to vary the cus of individual meetings. Thus the filmmaker's wn character and conflict, social or political issues at determine human behavior, philosophical positions as they affect one's life, and our own subjective dividual or group responses have all been emphazed in one or another discussion.

A combination of personal preferences and the nature of the film in question seems to determine the direction of the discussion. For example, *A Clockwork range* stimulated a discussion of the tension between ehavior control and human freedom in psychotherapy; *Deliverance* was discussed from the viewpoint of e four protagonists representing contrasting facets of e male personality; *Shampoo*, with its prominent featuring of Nixon and Agnew on TV, while the hero, George, is undone by his efforts to be everyone's friend, was discussed as a conscious/unconscious comment by Warren Beatty on the 1972 presidential campaign in which he was significantly involved; and Polanski's *The Tenant* was seen as offering psychodynamic insights through an externalized representation of the internal dynamics of paranoid schizophrenia. As a change of pace, the play *Equus* was discussed with actors from the American Conservatory Theatre of San Francisco in attendance; they added significantly to the discussion.

EVALUATION

To assess the value of such a seminar, questionnaires were mailed to the 36 residents to whom the seminar had been available during their training. Of the 31 residents who returned the questionnaire, 23 had attended more than half of the sessions and only 2 had never attended. Of those who had attended, all answered that they felt a cinema seminar was a valuable part of a psychiatric residency curriculum and would include such a seminar in a curriculum if they were designing it. The most common reasons given for the value of the seminar were that it helped to broaden the resident's perspective to include humanistic, social, and philosophical levels; it served to relate psychiatric insights to everyday life; it provided a useful opportunity for socialization with professional peers; it increased knowledge of unconscious dynamics; and it stimulated creative thinking.

COMMENT

Contemporary cinema, the vanguard of current artistic media, has great value for those learning psychiatry. Films provide an enjoyable, intense, and varied body of material without associated clinical responsibility. When psychiatrists in training or beyond want to comprehend the sources and form of humanistic imagination, integrate this with the directions of society in the 1970s, and share it all with those close to them, they are well advised to study the cinema.

Pseudoepilepsy: A Study in Adolescent Hysteria

BY MEIR GROSS, M.D.

Of 19 adolescents with diagnosed psychogenic seizures, 13 had hysterical convulsions and 4 had amnesiac fugues. Sixteen of the patients were given a diagnosis of hysterical neurosis; 2, process schizophrenia; and 1, borderline psychosis. Thirteen of the patients were initially diagnosed incorrectly as having epilepsy and were treated for an average of 15 months with anticonvulsant medication. The therapist should always consider the possibility of psychogenic factors in children and adolescents who suffer from seizures.

THE NEUROLOGIST, especially the one who works with adolescents, may be confronted with the diagnostic dilemma of how to differentiate between real epileptic seizures and seizures that are psychogenic or functional in origin. The adolescent patient may complain convulsions associated with complete blackout a amnesia to the time of the spell, while the EEG do not show clear-cut evidence of epileptic activity shows only a nonspecific abnormality. The EEG mig show a nonspecific abnormality in a nonepileptic nc mal individual or hysterical patient. Should such a p tient be diagnosed as epileptic and treated with an convulsive medications? A decision to treat a patie for many years or for life with anticonvulsant medic tions is a very difficult one, considering the side effec of such medications, the restrictions on driving a everyday activities, the social stigma, unavailability jobs, etc. It is very important to rule out the possibili of epilepsy in psychogenic seizures, or so-call pseudoepilepsy. The correct diagnosis enables t adolescent who suffers from psychogenic seizures get the right treatment for the disorder and also i tensive psychotherapy to help him or her cope wi personal conflicts in a better and healthier way.

Psychogenic seizures are hysterical in nature. Th have components of dissociative reaction, conversi reaction, or both. Difficulties in diagnosing d

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received Feb. 6, 1978; accepted April 18, 1978.

Dr. Gross is Head, Section on Child and Adolescent Psychiatry, Cleveland Clinic, 9500 Euclid Ave., Cleveland, Ohio 44106.

0002-953X/79/02/0210/04/$00.45 © 1979 American Psychiatric Association

ciative reaction or conversion reaction as hysterical urosis stem from the fact that the physician is not le to see the disease as part of the patient and does t recognize the patient as a whole person.

If the diagnostician concentrates only on the symptns, trying to classify them in an entity of a disease, or she is liable to misdiagnose the problem. The tient should be viewed and evaluated as a person. ıe symptoms should be weighed as to their value to ɜ patient and how the patient views the symptoms. ves he or she have indifferent feelings toward the seires (la belle indifference)? Is there any secondary in from the symptoms? Does the patient have an unrlying conflict that is being temporarily dealt with by veloping the symptoms? What is the symbolic eaning of the symptoms to the patient? What type of rsonality does the patient have, and what kind of fense mechanisms does he or she tend to use? Is the tient using denial, repression, and suppression as his her main repertoire of defense mechanisms? If the ınician will consider these questions when evaluating ıe patient, it is most likely that he will be able to corıctly diagnose the existence of hysterical seizures.

HE SUBJECTS

Within a period of 2 years, 19 adolescents suffering ɔm psychogenic seizures were diagnosed at the eveland Clinic. The 14 girls and 5 boys ranged in age ɔm 14–18 years (mean=15.79). In all but 2 of the paɜnts there was evidence of an underlying conflict. In ɔases one or both parents were overprotective, overɜmanding, and strict. One girl had been molested by ɜr stepfather, and another had been raped by her natal father while he was drunk. Two girls had recently ɜparated from their boyfriends. In 4 cases the parents ıd recently divorced. Two boys with low IQs were iling at school and felt hopeless about being able to ɔpe with their academic difficulties. One girl had not orked through her grief over the recent death of her other from breast cancer, and one boy had watched s mother's health deteriorate due to cancer.

Sixteen patients were given a diagnosis of hysterical ɜurosis; 2, schizophrenia; and 1, borderline psychos. Thirteen patients had histories of passing out, with ther convulsions or tremors. Four suffered from amɜsiac episodes, and 2 of these patients also had mulple personalities (1 had 2 personalities and the other ıd 3). One patient had spells of feeling "frozen," uttering, and hallucinating; 1 had fainting spells.

Thirteen of the patients were treated with antiɔnvulsive medications for 3–48 months (averge=15.54 months). Six were not given anticonvulsive edications since the proper diagnosis was made and pilepsy was ruled out. Twelve patients were treated y conventional psychotherapy, either insight oriented supportive; 5 of them also received neuroleptic or ıtidepressant medication. Seven patients were eated primarily by hypnotherapy.

DISCUSSION

From the description of these patients, it is clear that not all of them had hysterical neuroses; and if one would classify the personality patterns of these patients, not all of them would be categorized as having hysterical personalities. As Chodoff (1) noted, hysterical features appear in patients with other than hysterical personality types. Moreover, hysterical symptoms can be one of the signs of a developing borderline psychosis or schizophrenia, as seen in 3 of the patients. Rock (2) suggested that if the criteria for conversion reaction (as part of the hysterical neurosis) are not met, then the disorder should be called conversion symptoms or part of another syndrome or entity, such as schizophrenic reaction.

The female to male ratio in the present study was 14:5, almost 3:1. In his report on conversion symptoms, Engel (3) cited a ratio of 2-3:1. Since ancient times females have been more prone to hysterical neurosis.

Most of the patients in the present study were in late adolescence. Bernstein (4) has noted that this period is vulnerable to hysterical convulsions; it appears that the adolescent's turmoil is then at its peak. The struggle for self-identity and role differentiation is quite stressful for the adolescent. The adolescent is striving toward independence, while being afraid to give up the previous dependencies. The period of adolescence is one of changing behavior, lability of mood, and fragile, changing defenses (5).

The conflict area during adolescence can include separation from a boyfriend or girlfriend, grief, and divorcing parents. Passing out or change in level of consciousness during the seizure symbolizes the adolescent's need to get away from the conflictual situation. Change in level of awareness is the dissociative component of the seizure. The motor convulsion is the conversion reaction component, and it serves to release tension or anxiety. The mechanism is functional in origin and is created by the adolescent's need to use denial, repression, and suppression as the main defenses. The conflict is thus passed to the unconscious. Not one of the patients in the present study was malingering, since the process of producing the symptoms was completely unconscious.

Once the symptoms occur, there is a reduction in anxiety (the primary gain). Instead of expressing anxiety, the patient shows indifference to the symptoms. If the patient benefits from the sick role (e.g., gets more attention, is able to control the environment or manipulate family members), he or she may continue to take advantage of it (the secondary gain). Being sick helps the patient to regress and become dependent, which satisfies his or her dependency needs.

Thirteen of the patients were first diagnosed as epileptics. There was no evidence of epilepsy on any of the EEGs, but the treating physicians still considered the condition as organic and tried to treat it as such. Only after there was no response to treatment did they

refer the patients to the Cleveland Clinic's child neurologist, who requested psychiatric consultation. The first treating physicians showed denial of the possibility of functional problems in the patients. They tended to make diagnoses by exclusion and not by considering the patient as having an emotional conflict. Rock (2) also noted such attitudes by the treating physicians.

Diagnosis can be made using positive signs and symptoms, even without the elimination of organicity first. There is always the possibility of superimposed functional pathology in addition to physiological disorder (6). Hysterical convulsions should be suspected whenever there is no biting of the tongue and no fecal or urinary incontinence. Such seizures are less sudden in onset, and there is usually no bodily injury associated with them. Postconvulsive stupor or sleep is absent, and occasionally subjects may recall the event.

In 7 of the patients in the present study, hypnosis was also used in making the differential diagnosis. Schwartz and associates (7) noted that both epilepsy and hysterical convulsions can be activated by hypnosis and that the EEG of epileptic patients, but not hysterical patients, will show paroxysmal activity.

Schneck (8) suggested the use of hypnosis for the differential diagnosis of psychomotor epilepsy. He noted that convulsions can be induced during hypnotic trance; the epileptic patient cannot stop them by suggestion, but the hysterical patient can. Sumner and associates (9) noted that hysterical patients could recall what happened during their spells while in hypnotic trance but that the epileptic patients could not. They also noted that the hysterical patients tended to be more hypnotizable. The 7 patients with hysterical convulsions who were diagnosed by hypnosis were very hypnotizable, and all of them could recall the previous spells, including what had happened during them while the patients were under hypnosis (10).

Psychogenic convulsions are much more common than they are thought to be. Hysterical symptoms in children are considered rare and have been on the decrease since the rigid Victorian age (11).

Proctor (12), in a review of the literature up to 1957, noted that "there is no good bibliography available pertinent to childhood hysteria." Stevens (13) also mentioned the paucity of literature on conversion hysteria from about 1957–1967.

Is childhood hysteria as rare as one might assume from a review of the literature? It is my opinion that if more attention were paid to the possibility of childhood hysteria, it might be diagnosed more frequently. In our study 13 patients received anticonvulsant medications for an average of 15.5 months before the correct diagnosis was made, and it was made primarily because there was no response to the drugs.

Treatment of psychogenic seizures is needed to prevent fixation of symptoms. The untreated patient may hold on to his or her secondary gain, but also will be limited for life. The patient may prefer to see himself or herself as a real epileptic, will limit his or her activities, and regress in social contacts to the point of soc isolation.

It is important to reassure the child and the paren Usually the child will not accept the existence of a emotional factor in his or her condition. He or she (ten refuses to see a psychiatrist, and for this reason t first stage of therapy should focus on fostering rapp with the patient and building a good alliance that w be the cornerstone for further therapy. After the p tient's resistance is reduced, he or she will be mc ready to give up the pathological defenses. It is imp tant to reassure the parents about the very good pr nosis when the child becomes involved in therapy. the parents support the therapist it will be easier f the adolescent to give up the secondary gain, esp cially if he or she cannot manipulate them any mor

Treatment usually takes 3–6 months. The removal the seizures is not enough; follow-up is necessary order to help the patient solve the main conflict th caused the appearance of symptoms. Once the patie gives up the secondary gain he or she is more ready consider changing his or her defenses. The defenses children and adolescents are more labile than those adults and more rapid change is possible. Brief thera is usually sufficient; however, the more severe cas may require 6 months or more of therapy. In the pr ent study 6 months of therapy were enough to elir nate symptoms and enable the patients to devel healthier defenses and coping mechanisms.

CONCLUSIONS

Emphasis should be put on early diagnosis of p chogenic seizures; it is common to diagnose them c rectly only after treatment with anticonvulsant me cations has failed. With early diagnosis the progno is fairly good, since the symptoms are not yet fixa in the child's personality. If the emotional conflict dealt with in the first stages of the disorder, there less need for the patient to hold on to his or her s ondary gain. It is important that the practitioner mo from an organic point of view to an evaluation the child's whole personality and social and envir mental background. This will help the therapist making the right diagnosis early and in starting thera when it can still change ego defenses and improve t prognosis.

hild Psychiatry Education for General Residents

JOHN F. GREDEN, M.D.

ere is continuing debate about what child chiatry experiences should be included in a general idency. The author describes the program at the iversity of Michigan in an effort to provide some ights into the interface between child psychiatry d general residency training. This program is que in several respects: a 12-month rotation in ld psychiatry is offered, and the faculty size and dget of the youth services are comparable to those he adult services. A survey of all residents and ulty pointed up numerous disagreements as to the gth of the rotation and priorities in curriculum. The hor discusses the influence of the various npetitive processes on the educational program.

HAT CONSTITUTES an ideal child psychiatry experie ce for general residents? This question has perxed generations of educators.

Although child psychiatrists began their fight for ognition as a distinct professional discipline more n 50 years ago (1, 2), and great strides have been made in some areas, in many educational programs the impact of child psychiatry in training general residents has been minimal. There are marked differences, both subjectively and objectively, in child psychiatry experiences among general residencies (3). Most programs give verbal support for learning child psychiatry, but in only a few is this actually translated into substantial didactic and clinical emphasis.

More than a decade ago Lawrence Kubie confronted this issue by advocating that *all* residents launch their training by studying infants and children (4). He also suggested that residents work with adolescents after the initial phase of learning child development, and only then would they evaluate and treat patients with neuroses and psychoses. As demonstrated by continued debate, Kubie's proposals did not resolve the problem. Had his suggestions been widely accepted, child psychiatry experiences for general residents would certainly be longer, more intense, and more influential than they currently are. Instead, it is still an exceptional residency that offers extensive child psychiatry experiences.

A program that has emphasized child psychiatry training for general residents is the one at the University of Michigan. Consequently, consideration of Michigan's program might provide some insights into the still-nebulous interface between child psychiatry and general residency training.

Several training factors seem unique to Michigan. Perhaps most important, from 1972 to 1977, almost all of the general psychiatry residents spent their entire second year on what is known as the youth service. The youth service at Michigan consists of child and adolescent programs. During the 12-month youth rotation, there is an emphasis on developmental theory, psy-

sented at the 130th annual meeting of the American Psychiatric ociation, Toronto, Ont., Canada, May 2–6, 1977. Received Sept. 1977; revised April 14, 1978; accepted May 18, 1978.

Greden is with the Department of Psychiatry, University of higan Medical Center, Ann Arbor, Mich. 48109. At the time this k was done he was Director of Residency Education; he is now ociate Professor of Psychiatry and Medical Director, Clinical lies Inpatient Unit and Day Hospital Program.

: author acknowledges the assistance of Larry Brain, M.D., who ticipated as a member of the subcommittee conducting this evalon, and of Deborah Bland, who compiled the survey data.

0002-953X/79/02/0213/04/$00.45 © 1979 American Psychiatric Association

chodynamics, inpatient and outpatient work with children and adolescents, and family therapy. The experience of the general residents is virtually identical to that of the first-year child psychiatry fellows. In essence, by the time the general resident at Michigan had completed the three-year program, he or she had also completed one-half of a child psychiatry residency. Most general residents have considered the experience educationally excellent.

A second unique feature is that the youth service is proportionately larger than that found in many other programs and is geographically distinct. With more than 50 faculty and 13 child fellows, the youth service budget is comparable to that of the adult service. The child psychiatry program at Michigan clearly does not lack visibility or strength. Perhaps this explains in part why a 12-month child rotation was initially instituted.

Since this program has been in operation for several years, it is now possible to assess it from a historical perspective, however brief. Soon after implementation of the program, many adult faculty members (perhaps predictably) began to criticize the length of the youth rotation. A major complaint was that with one-third of their residency being spent on youth services, general residents lacked the necessary time to learn basic principles of adult psychiatry. The residents themselves complained of having no time for electives. Thus a seeming paradox developed. Most of the adult faculty members acknowledged that general residents should learn child psychiatry. Most also acknowledged that the general residents *were* mastering child psychiatry exceedingly well. However, most simultaneously found themselves advocating a reduction in this apparently worthwhile experience. The beleaguered resident group frequently appeared to be caught in the middle of this argument.

To evaluate child psychiatry training for general residents, and to simultaneously collect data to assist the residency education committee in the formulation of an experiential core curriculum, a subcommittee was formed to assess this issue. A questionnaire was distributed to all faculty and residents. This paper briefly reports the subcommittee's findings, together with my subjective impressions of the issue, stemming from the perspectives of having chaired the subcommittee and later directing the general residency education program.

METHOD

In 1975 a 4-page questionnaire was distributed to various faculty and resident members at the University of Michigan Department of Psychiatry. Respondents were arbitrarily divided into 4 subgroups: adult-oriented senior faculty, general psychiatry residents, youth-oriented senior faculty, and youth fellows. The number of forms completed and the percentage of completion for each subgroup were as follows: adult senior faculty—26 (84%), youth senior faculty—16 (29%), youth fellows—10 (91%), and general psych try residents—21 (75%). A total of 73 questionnai were returned (a completion rate of 58%).

Respondents were asked to do two things: rate th attitudes about the child psychiatry rotation on a point Likert scale ranging from "strongly agree" "strongly disagree," and establish priorities for psychiatric approaches traditionally included wit general residencies. These approaches included dev opmental theory of childhood and adolescence, patient treatment of adults, outpatient evaluation children, outpatient treatment of children, outpati treatment of adults, drug therapy of children, dr therapy of adults, crisis intervention of adults, cri intervention of children and adolescents, treatment adults as parents, and youth inpatient treatment. Ea item was rated on a 5-point scale (1=highest prior and 5=lowest priority). The form emphasized that r ings should be for general psychiatry residents, r child fellows. We then used mean scores to compil sequential ranking of priorities.

RESULTS

Questionnaire Assessments

There was some agreement about priorities am child psychiatry faculty and residents and among ad oriented faculty and residents; however, there was a a great deal of disagreement. All 4 subgroups essentia agreed that the outpatient treatment of adults was very high priority (mean rating=1.3). In contrast to relative unanimity, child psychiatry faculty rated velopmental theory of childhood and adolescence h enough to place it second on their listing; child p chiatry fellows ranked it first. Adult-oriented fac and residents ranked it only fifth and sixth, respecti ly. Even more striking, adult faculty had a mean ority rating of 1.77 for drug therapy of adults, rank it second, and general residents ranked it third. A nificantly lower percentage of youth-oriented fac and fellows considered this an important item, h ever; they ranked it ninth and fifth, respectively. C patient evaluation of children was considered of m lower priority among adult-oriented psychiatrists t among child psychiatry staff and residents. Drug th apy of children and inpatient treatment of child received the lowest ratings and subsequent rankin among all 4 subgroups. In summary, 3 of the firs priority items among youth-oriented faculty pertain to child psychiatry. General residents had no you oriented items among their first 5 items, and adu oriented faculty had only 1 (teaching developmer theory).

When asked about the ideal duration for a yo services rotation for general residents at Michig 71% of the adult-oriented faculty and 60% of the gen al residents said that the current rotation of 12 mon should be shortened. None of the youth-oriented f ulty expressed this sentiment; indeed, 20% felt tha

ar was inadequate and that the rotation should be ngthened.

bjective Impressions

These questionnaire assessments provide only a rtial story of child psychiatry training for general sidents at Michigan. Since this simple study was nducted in 1975, there have been periodic deliberions about changing the rotation. As I observed and rticipated in these debates, I was struck by several ctors. First, the issue of child psychiatry training for neral residents often became confounded with anher ideological dispute, namely, analytic psychiatry rsus biological psychiatry. The child residency segent seemed to have been identified with psychonamic education, and many adult service segments ith "medical psychiatry." Whether these observaons were correct scarcely seemed to matter when ttle lines were drawn.

A second major observation was that child psychiasts who defended the length of their rotation were ncere in their belief that this was best for the general sidents. Service considerations seemed minimally portant. Most youth-oriented faculty and fellows arly believed that the best way to prepare for a caer in general psychiatry was to have extensive exsure to child and adolescent psychiatry. However, I ted that adult-oriented faculty members just as fernly believed that residents should have a shorter uth-oriented rotation. Many enthusiastically pleadfor greater exposure to such topics as substance use, geriatric psychiatry, forensic psychiatry, neuchemistry, neuroendocrinology, aftercare of chronic tients, consultation with their medical colleagues, d psychiatric research.

ISCUSSION

This assessment of the role of child psychiatry traing in the general residency program at the University Michigan perhaps demonstrates that the issue will t be resolved through simple expansion of child psyiatry rotations. The experience has value for other ograms. Historically, child psychiatrists have had to ercome territorial guarding to teach their principles general residents. In some departments their victory s been only partial. At Michigan, however, the child ychiatry segment of the department has truly atned recognition, and a different explanation must be rmulated to explain current conflicts.

I have concluded that the process is loosely comrable to a marital conflict involving issues of dirce. Unfortunately, the marital feud often includes a spute over the custody of the children. In divorce sputes the child is commonly an innocent victim (5). milarly, in this educational dispute the resident bemes an innocent victim. To carry the analogy fur-er, adult- and youth-oriented faculty seem to disree about such issues as what the resident should read, what clothing he or she should wear (such as a white coat), where he or she should "go to school," what ideology should be professed, and where the resident should spend the majority of his or her time.

In their influential publication *Beyond the Best Interests of the Child* (5), Goldstein and associates concluded that it was important to protect the child's relationships with at least one parent during a divorce. At the risk of oversimplifying a complex educational issue, I would suggest that a similar need exists among psychiatry residents in solving disputes about youth-oriented experiences in their training. Both the child of divorcing parents and the psychiatry resident in an educational dispute should be able to identify one major decision maker. For *general* residents, the role of "parent" should be filled by *general* psychiatrists. It is clear that the advice and consent of child psychiatry staff is needed to compile the best program. We cannot return to the days of resistance to child psychiatry training for general residents. Nevertheless, if we keep intact the ultimate question of what a resident is being trained for, it seems that a mini-version of a child residency is not in their best interests.

In my opinion, their best interests are served by the integrated learning of those parts of child psychiatry which enhance their treatment of adults and older adolescents, rather than those which provide skills in the treatment of children or young adolescents per se. In considering this, it appears that the program laid forth by the adult-oriented faculty in the present survey is the most acceptable. Adult outpatient treatment, crisis intervention, and psychopharmacology would head the list of priorities, but emphasis would also be given to developmental theory of childhood and adolescence. Somewhat lower on the list but still of medium to high priority would be working with adults as parents, outpatient evaluation of children, and crisis intervention with youths. Drug therapy of children and inpatient treatment of children and adolescents would be low-priority items, and in a crowded curriculum they would be excluded if time were unavailable. (As pharmacotherapy of children becomes more thoroughly investigated, however, this priority may have to be reconsidered.) Certainly no one can dispute the fact that any general resident would profit from a rotation on a child inpatient unit. Nevertheless, in time-limited residencies continued consideration must be given to the ultimate question of what knowledge, skills, and attitudes are most important at the completion of residency. I do not believe that inpatient treatment of children should be included on this list.

If the previous analogy can be continued for one final step, my ultimate wish is that the "parental disagreement" cease. For this to occur, agreement will have to be reached in some fundamental areas. Since ideological differences inevitably will continue, we need to intensify our assessment of what residents ultimately do or should be doing in the treatment of patients (6, 7). If adult- and youth-oriented psychiatrists cannot agree on what psychiatric residents should do

after training, they certainly will not agree about what has the highest priority during residency. If reasonable agreement were reached, the next question would be whether residents have the knowledge, skills, and attitudes to do what is required. Using such information, an irreducible experiential core curriculum could be devised to stipulate the educational experiences in child psychiatry that every resident should have to practice general psychiatry. One could then attempt to answer such difficult questions as How many children need to be evaluated? What ages should they be? When should these evaluations be done? Should normal families be followed? What is the role of drug therapy for children?

Considering the lack of attention given to child psychiatry generations ago, it is amazing that a custody battle could actually be developing in certain programs throughout the country. Nevertheless, this appears to be the case. In his extensive dissertation on traditionalism, Kubie (8) noted that once a program becomes operational it is difficult to modify. He attributed this resistance to "the hold on seniority rights which no one ever gives up willingly." At one point in psychiatric history, this pattern probably prevented child psychiatry from assuming its rightful place in educational programs for general residents. Data from this study suggest that the opposite can also occur. Child psychiatrists have the potential to become traditionalists, too. If this is to be prevented, we must remind ou selves what the educational end product of our effo should be, namely, a competent general psychiatr with a thorough understanding of developmental the ry and family dynamics, with fundamental skills f child evaluation and diagnosis, and with adequate tin to master the multitude of other areas now proven be relevant to the treatment of adult patients.

cute Extrapyramidal Reactions with Fluphenazine Hydrochloride and Fluphenazine ecanoate

ALAN J. GELENBERG, M.D., JOANNE C. DOLLER, R.N., M.S., NINA R. SCHOOLER, PH.D., ARLENE MIESKE, R.N., M.S., JOANNE SEVERE, AND MICHAEL R. MANDEL, M.D.

Extrapyramidal symptoms (EPS) have been report- to occur in 20%-43% of patients treated with oral enothiazines (1–3) and are probably even more com- on with the piperazine phenothiazines (3, 4). For er a decade, two long-acting injectable piperazine enothiazines, fluphenazine enanthate and deca- ate, have been available for the treatment of schizo- renia. The incidence of EPS with the fluphenazine ers has been reported to be approximately 50% (5), t Ayd has stated that the long-acting fluphenazines use no more EPS than oral antipsychotics (6).

In this paper, we will present an analysis of EPS that occurred during the acute-treatment phase of a collaborative study which compared fluphenazine hydrochloride with fluphenazine decanoate. Two questions will be addressed:

1. Are there differences in occurrence of EPS between oral and depot fluphenazine?
2. Are patient characteristics such as sex, race, or age related to differential occurrence of EPS?

Method

The design of this four-center collaborative study has been described in detail elsewhere (7). In brief, 290 male and female schizophrenic inpatients, ages 18–55, entered the study when they were experiencing a psychotic episode. After they gave written informed consent, all patients were treated for 1 week with oral fluphenazine HCl in dosages that reached at least 15 mg by day 3. Patients were then randomly assigned in blind fashion to one of two groups and given continued oral fluphenazine or fluphenazine decanoate. Each patient ingested tablets twice daily and received an injection at least every 3 weeks. The fluphenazine HCl group received placebo injections and the decanoate group took placebo tablets. Dosages were adjusted according to clinical response and without a fixed ratio between oral and injectable fluphenazine. Doses ranged from 5 to 60 mg/day for oral fluphenazine and 12.5 to 100 mg every 3 weeks for injections. Benztropine mesylate, up to 6 mg/day, was used only if clinicians thought it was necessary to control EPS.

Assessments. After initial baseline screening, including psychiatric diagnosis and history, patients were rated by a research psychiatrist and a nurse at weeks 1, 4, and 7. The doctor and nurse each independently completed the Dosage and Treatment Emer-

ceived April 13, 1978; revised Sept. 8, 1978; accepted Sept. 25, 78.

gent Symptoms Scale (DOTES) of the Early Clinical Drug Evaluation (ECDEU) battery (8). The present report will deal only with 1) DOTES items that reflect EPS—increased or decreased motor activity, rigidity, tremor, increased salivation, and akathisia, and 2) data on age, sex, race, history of EPS, and previous use of antiparkinsonian drugs. Signs and symptoms are rated on the DOTES by a 4-point scale ranging from 0 (not present) to 4 (severe).

Statistical analysis. Chi-square analyses (using Yates' correction for continuity where appropriate) were computed between treatments (oral or depot) for each symptom as rated by both the physician and nurse at weeks 1, 4, and 7. Eleven patients were removed from treatment because of side effects; since these cases could have affected the results, chi-squares were calculated both including and excluding them.[1] Analyses were also done for three symptom clusters from the DOTES: 1) increased motor activity and akathisia (the akathisia cluster), 2) decreased motor activity, rigidity, tremor, and increased salivation (the parkinsonian cluster), and 3) a central nervous system cluster (8). Finally, correlations between each of the EPS and age, race, sex, history of EPS, and history of antiparkinsonian drug use were examined.

Results

At the end of the first week of the study, when the double-blind phase was initiated, the mean initial dose for patients in the oral fluphenazine group (N=147) was 24.4 mg/day (SD=10.2). The mean initial injection in the decanoate group (N=143) was 33.6 mg (SD=13.7). At the end of the fourth study week, the mean oral dose was 24.2 mg/day (SD=13.4, N=139), and the mean injection was 35.5 mg per three weeks (SD=19.21, N=134). By the end of the seventh week, the mean oral dose was 24.2 mg/day (SD=14.8, N=122), and the mean decanoate dose, 35.1 mg per three weeks (SD=19.5, N=118).

Analyses of symptom differences between the two groups revealed a few scattered treatment effects ($p \leq .05$), but none that was significant for both doctors' and nurses' ratings at the same rating period and none that remained over any of the periods. This was true whether or not the 11 patients who dropped out because of side effects were included in the data analysis.

Based on analyses of physicians' ratings in the cluster groups, 21.2% of patients on oral medication suffered from akathisia at week 1, 19.5% at week 4, and 25.2% at week 7. By contrast, 22.7% of decanoate patients showed akathisia at week 1, 22.7% at week 4, and 27.5% at week 7. These differences are not statistically significant. A comparable analysis of the parkinsonian cluster revealed that 27.4% of the patients on oral therapy showed parkinsonian signs at week 1, 41.5% at week 4, and 31.9% at week 7. Parkinsonian signs were present in 23.4% of decanoate patients week 1, 25.7% at week 4, and 35.5% at week 7. Agai differences were not statistically significant. Similar analysis of the CNS cluster revealed no statistica significant differences between treatments. Corre tions between doctors' and nurses' ratings were co sistently high and statistically significant.

The following EPS were correlated, in both phy cians' and nurses' ratings, with benztropine usage: A ter the first treatment week of nonblind oral fluphen zine, 57% of the patients were receiving benztropin and akathisia and rigidity were significantly associat with benztropine prescription. At week 4, in the o fluphenazine group, use of benztropine (70% of the p tients) was associated with decreased motor activi rigidity, and tremor, while among the decano group, use of benztropine (64% of the patients) w correlated with akathisia and rigidity. By week 7, al thisia and rigidity were associated with benztrop use (74% of oral and 69% of decanoate patients) both forms of fluphenazine. Abnormal involunta movements were associated with *less* benztropine u

Analyses of demographic data demonstrated no s nificant relationship between EPS in this study and p tients' age, race, sex, history of EPS, or previous an parkinsonian drug use.

Discussion

We found no significant differences in the occ rence of akathisia or Parkinson's syndrome within t first 7 weeks of drug therapy between patients trea with fluphenazine decanoate and those treated w fluphenazine HCl. In addition, we found no correlat between the occurrence of any of the signs of th two disorders and age, sex, race, history of EPS, previous antiparkinsonian drug use. Benztropine u was significantly related to the presence of EPS, as have reported earlier (7). However, since this tre ment was based on clinical indication, no conclusi can be drawn about the effectiveness of benztropir

Our data are essentially in agreement with Ay finding that the incidence of EPS did not differ sign cantly between patients on fluphenazine decano and those on oral preparations. (It is conceivable t the enanthate preparation may be associated witl higher incidence of EPS, as has been reported [5], we did not assess this.) We also did not find a high cidence of akinesia, as measured by decreased mo activity, although we were not looking for some of more subtle behavioral manifestations that Rifkin a associates subsumed under the term "akinesia" 10).

In summary, data from this study suggest that, spite their relatively high incidence, akathisia a Parkinson's syndrome are not serious problems dur the first 7 weeks of treatment with either fluphenaz HCl or fluphenazine decanoate. Furthermore, long-acting ester did not produce more EPS than oral form.

[1]Other patients who did not complete the study were removed because of failure to improve or for administrative reasons.

Hypnopompic Hallucinations and Treatment with Imipramine

BY ROBERT SCHLAUCH, M.D.

Hypnopompic hallucinations occur during the owsy state just before awakening and are thought to e related to hypnogogic hallucinations, which occur st before one falls asleep. The hallucinations are usuly visual, although they may also be tactile or audiry, are often well-formed, and appear to be coming ward the individual. They occur in normal individuls, but their incidence is difficult to determine beuse of the general reluctance to report hallucinaons. However, evidence suggests that most people ill experience hypnogogic phenomena at some time their lives (1).

Although hallucinations as a result of therapy with icyclics were described during the first decade after e introduction of these drugs, little note of this phenomenon has been taken recently. Recent reports ave dealt largely with psychoses resulting from atronic side effects of tricyclic antidepressants. I wish to ll attention to tricyclic-related hallucinations that do t result from toxicity. This phenomenon may have levance to the therapeutic effects of these drugs as ell as factors in compliance.

ase Report

Ms. A, a 61-year-old woman, was referred to me because depression of 2 years' duration. She had been taking amiptyline, 50–100 mg h.s., for 6 months without significant nefit or side effects.

Ms. A had an obsessive-compulsive personality with a pical endogenous depression. She complained of insomnia, crying spells, worry, anxiety, preoccupation, and agitation. She had no psychiatric history before her depression and had never hallucinated. Her father was an alcoholic, but there was no other mental illness in the family. Both parents and her brother had died 25 to 30 years before. She had a healthy 68-year-old sister. Neither of her two daughters had significant mental illness.

I prescribed imipramine, 150 mg h.s., and after 6 weeks Ms. A described herself as "1,000% improved"; she had returned to her normal affect and functioning. However, at this time she began to awaken about once a night, between 2 and 4 a.m. Initially, she saw her bedroom bathed in a red glow, although she knew it should be dark. She saw one to three people around the room, dressed in white. Some were strangers and others were known to her.

She became quite frightened when these figures came toward her, and she would close her eyes, "turn away or go to sleep." If very frightened, she would "wake up." Once she spoke to her husband in Polish "so that they wouldn't understand me."

Ms. A suspected the imipramine had something to do with these frightening experiences. She considered stopping the medicine but confided in her daughter, who convinced her to tell me about it. Her dose was then decreased to 100 mg h.s. without change in her affect, but the hallucinations persisted and even increased from about two to four a week. Therefore, after 6½ months, the dosage was changed to 50 mg q.a.m. The hallucinations stopped within 3 days, but after 3 weeks her depression had returned. I again placed her on 150 mg of imipramine h.s. and the hallucinations began after 3 days, followed by gradual disappearance of her depression.

At the time her hypnopompic hallucinations began, the patient was given a complete medical evaluation, including physical examination, chest X ray, ECG, urinalysis, blood chemistry, electrolytes, CBC, T_3, T_4, and FTI. All were normal except an ECG that showed incomplete right bundle branch block.

After she had been taking imipramine for 10 months, the frequency of her hallucinatory experiences had decreased to about once a week. Six months later her hallucinatory experiences had decreased to about one a month, and the imipra-

ceived Sept. 28, 1978; accepted Nov. 6, 1978.

. Schlauch is Clinical Associate in Psychiatry at Massachusetts neral Hospital, Instructor in Psychiatry at Harvard Medical hool, and Assistant Director of the Freedom Trail Clinic, Lindmann Mental Health Center, Boston, Mass. He is also in private actice at Westwood Lodge, 45 Clapboardtree St., Westwood, ass. 02090.

0002-953X/79/02/0219/02/$00.35 © 1979 American Psychiatric Association

mine was again reduced to 100 mg h.s. However, within 2 months, her depression had returned (she had had one hallucinatory experience) and she was again given 150 mg of imipramine, h.s. Within 1 month she was again well and at the time of this writing, 2 years after imipramine therapy was initiated, she remains well and experiences hypnopompic hallucinations about once a month. At no time during her treatment has she experienced disorientation or excessive anticholinergic symptoms.

Discussion

This case demonstrates a clear relationship between the onset of hypnopompic hallucinations and imipramine therapy in a patient without a history of hallucinatory or hysterical symptoms.

In an extensive review of visual hallucinations with imipramine, Klein (2) summarized seven reports in which most patients who hallucinated were on high-dose imipramine therapy (250–400 mg/day). In his own study, 12 of Klein's 209 patients developed hallucinations. Nine of these were schizophrenic and 11 of the 12 were taking 300 mg/day of imipramine. The 12th patient developed hallucinations after 6 days on a dose of 150 mg/day. Klein noted no evidence of "confusion approximating an organic mental syndrome" in his patients, who did not differ significantly in age, sex, or diagnosis from the rest of his sample. In 9 of the 12 patients, the hallucinations were dose-dependent; decreasing the drug to 150 to 200 mg/day terminated the phenomenon.

I believe that several factors hamper our understanding of the occurrence of hallucinations in patients taking imipramine. First, there has been a failure to differentiate the various types of hallucinations, which include 1) hallucinations due to anticholinergic side effects, 2) hallucinations in psychotic individuals or those with a history of hallucinating, and 3) hallucinations in individuals with no evidence of psychosis, hysteria, or organicity.

In addition, the fact that these phenomena are hypnopompic or hypnogogic has not been attended to sufficiently. It is known that imipramine increases stage 4 sleep (3) and is associated with an increased incidence of stage 4 phenomena (4, 5). Because hypnopompic hallucinations are a stage 4 phenomenon it is reasonable to expect them to occur with imipramine therapy.

The antidepressant effects of REM deprivation and the REM-depriving effect of imipramine have be well noted (6). Vogel (7) has postulated that this RE deprivation is the primary mode of action of the t cyclic antidepressants.

However, since depression is associated with an i creased frequency and duration of wakefulness and marked decrease in stage 4 sleep (8), this sleep sta may play an important role as well. This case stu shows a clear correlation between imipramine dosag recovery from depression, and stage 4 sleep phenom na. Is it not possible that enhancement of deep sleep therapeutic for many depressives but is observable only scattered cases?

In addition to suggesting a mode of action of imipr mine, hypnopompic hallucinations may also play role in patient noncompliance. Most people are frigh ened by hallucinations, and should a patient correct associate his medicine with his hallucinations he mig assume he was getting worse and therefore disconti ue the drug. If he does not discontinue therapy alt gether, he might still be reluctant to report the hallu nations to his doctor. Psychiatrists should be aware hypnopompic hallucinations and question patien about them if this appears indicated. Patients shou be reassured to learn that the hallucinations are b nign, occur less often with prolonged therapy, a mark improving rather than deteriorating men health.

ncidence and Morbidity of Self-Induced Water Intoxication in State Mental Hospital atients

"Y C.J. JOSE, M.D., AND J. PEREZ-CRUET, M.D.

The syndrome of self-induced water intoxication is a stinct clinical entity that occurs almost exclusively in sychiatric patients. The syndrome consists of comulsive water drinking associated with symptoms of ater intoxication. Rountree's classic paper on water toxication (1) enumerated the symptoms as follows: stlessness, asthenia, polyuria, frequent urination, dirrhea, excess salivation, nausea, retching, vomiting, uscle tremor and muscle twitching, ataxia, tonic and onic convulsions, frothing at the mouth, helpssness, stupor, and coma. Since the first case report ppeared in 1938 (2), there have been relatively few ports of psychiatric patients with this syndrome. owever, the general impression is that the overall indence of self-induced water intoxication in psychiatc patients is much higher than the number of pubshed reports would suggest. This underreporting may flect the transient nature of the syndrome or lack of vareness or interest in this clinical condition. We ve investigated the incidence of water intoxication the long-term-care psychiatric population of a large idwestern state mental hospital in a metropolitan ea; we are not aware of any previous studies on the cidence and morbidity of water intoxication.

ethod

Nursing and medical staff of the nine long-term psyiatric wards of a state hospital were asked to provide e names of patients they thought were drinking wa r in excessive amounts. These patients were interewed and their charts were reviewed in detail for obctive evidence of compulsive water drinking and wa r intoxication. A patient was diagnosed as a mpulsive water drinker if 1) the staff of the ward and e patient both felt the patient drank water in excesve amounts or 2) the staff felt the patient was drinkg excessive amounts of water and there was docuented evidence of this in the patient's chart. Water toxication was diagnosed if the patient or the chart dicated a history suggestive of cerebral impairment sociated with excessive water consumption.

esults

Of the 239 patients surveyed, 16 (6.6%) had a consisnt history of compulsive water drinking; of these, 8 (3.3%) had symptoms of water intoxication. In addition to these 8 patients with self-induced water intoxication, data were obtained from 4 other patients from the same institution who were not included in the survey because they were not living in the long-term psychiatric wards at the time the survey was carried out.

The mean age of the 12 patients was 42 years (range, 22–54 years); 8 (67%) were female. Ten of the 12 (83%) carried a diagnosis of schizophrenia; the other 2 were mentally retarded. The most common mode of presentation of water intoxication was generalized seizures. Nine of the patients (75%) had a total of 16 incidences of water intoxication with seizures. Of the remaining 3 patients, 1 was found semiconscious following excessive water drinking and the other 2 had only the minor symptoms of nausea, vomiting, dizziness, and lightheadedness.

The clinical diagnosis of water intoxication was confirmed by measures of serum electrolytes in 8 patients (serum electrolyte determinations had not been done for the remaining 4 patients). A low serum sodium level was a consistent finding in these patients (mean=121 mEq/liter, range=110–131 mEq/liter, normal range =136–145 mEq/liter). Only 1 patient was investigated for the syndrome of inappropriate secretion of antidiuretic hormone, and the findings supported this diagnosis. The patient was a 43-year-old man with a diagnosis of paranoid schizophrenia who showed natriuresis (urine sodium=48 mEq/liter) and high urine osmolality (506 mOsm/kg H_2O) despite his low serum sodium (110 mEq/liter) and low serum osmolality (230 mOsm/kg H_2O). Renal and adrenal functions were normal and he did not show evidence of dehydration. Thus, all of the criteria for the diagnosis of inappropriate secretion of antidiuretic hormone (3) were fulfilled.

All 12 patients recovered without any apparent sequelae, despite multiple episodes in some cases. The disability lasted from a few hours to a few days.

Discussion

The present study supports the general impression that the incidence of water intoxication in psychiatric patients is much higher than the number of reports in the literature would suggest. Why only certain psychiatric patients with compulsive water drinking develop water intoxication is not fully understood. We have reviewed the syndrome of inappropriate secretion of antidiuretic hormone in relationship to psychiatry (4) and feel that at least in some cases of water intoxication, the inappropriate secretion of antidiuretic hormone induces the symptoms.

The present study also showed that the treating phy-

sician is not always aware of the syndrome. In some cases, the diagnosis had been delayed for years and the patients had undergone expensive and intrusive investigations and received prolonged, unnecessary anticonvulsive medications for seizures of undetermined origin that were almost certainly due to water intoxication. Electrolyte estimates at the time of the seizure in those patients with a history of compulsive water drinking are essential in establishing the proper diagnosis of water intoxication.

Insanity Plea: Legislators' View

BY RICHARD A. PASEWARK, PH.D., AND MARK L. PANTLE, M.A.

Although philosophic discourses on the plea "not guilty by reason of insanity" (NGRI) abound in the psychiatric and legal literature, there have been few empirical studies, most of which have examined the characteristics and disposition of persons who enter the plea. There have been, to our knowledge, no studies directed toward the beliefs held by individuals or groups about the plea.

The present investigation surveyed state legislators in Wyoming to ascertain their estimates of the incidence and success rate of the insanity plea in Wyoming and their beliefs about certain procedures that govern the operation of the plea.

Method

A questionnaire was mailed to all members (N=92) of the Wyoming state legislature in December 1977. The return rate was 35% (N=32). Although this is a minority return, we think that the responses provide some information on legislators' knowledge of the plea. Of the respondents, 27 were male, 3 female, and 2 did not specify their sex. Five were attorneys and 24 were not (3 respondents did not indicate occupations). Thirteen reported that they or members of their immediate families had been the victim of a crime at some time. The types of crimes they reported ranged from murder (one case) to petit larceny (five cases).

Results

In estimating incidence of the NGRI plea and its success rate, respondents were told that during the period considered (1970–1972) there were 21,012 felony indictments in Wyoming (1). The legislators' mean estimate of the number of persons who pled NGRI was 4,457.84, with a median of 3,025.50 and a range of 18,567. The mean estimate of the number of perso adjudicated NGRI was 1,794.28 (median=501.0 range=0–13,600). In fact, 102 defendants made th plea and only 1 was so adjudicated.

Consistent with respondents' overestimation of t frequency and success rate of NGRI plea was their sponse to the statement, "The insanity plea is used t much. Too many people escape responsibility f crimes by pleading insanity": 15 respondents agre strongly, 11 agreed somewhat, 2 disagreed somewh and 2 disagreed strongly.[1]

Asked whether "there is ever a situation in which person accused of a crime should be excused from sponsibility for it because of mental illness," 21 leg lators responded affirmatively and 10 negativel Thus, a large majority of legislators expressed agre ment with the basic philosophy underlying the NG plea.

As a group, the legislators were even more empha in rejecting the notion, as proposed in Illinois and N York, that acquitted NGRI defendants should treated in the same fashion as convicted individua Only 4 respondents agreed that "if a person has be found not guilty by reason of insanity to a crimi charge . . . the consequences and/or punishm should be the same as for a person found guilty of same crime who is not mentally ill"; 26 disagreed.

Respondents indicated a fairly good awareness procedures involved in the NGRI plea. Twenty-six the legislators indicated that either the jury or judge was responsible for the ultimate decision o defendant's sanity; two believed psychiatrists m the decision, and one thought it was the county torney. Most legislators were also aware of the d position of acquitted NGRI defendants. Nineteen

cated that the person is mandatorily committed to e state hospital until he/she is considered sane, nich is the requirement of a Wyoming statute. Ten ated that the NGRI patient was hospitalized for a pulated time; and 1 expressed the belief that the in-vidual was placed under the jurisdiction of the pro-tion department.

mment

Our results indicate that Wyoming legislators ossly overestimate the frequency and success rate of e NGRI plea in the state and seem to believe the fense is overused. However, a large majority still cribes to the basic philosophy of the NGRI plea. We spect the widespread publicity given by the media to e more notorious NGRI cases contributes to legisla-s' gross overestimates. Although it would be easy decry the lack of knowledge of legislators in this sphere, we believe that the blame rests with members of the mental health and legal professions. In this belief, we are influenced by the written statements of a number of legislators who returned uncompleted questionnaires with remarks indicating that their task was to promulgate law, while ours was to provide them with the appropriate data. Considering the extreme paucity of objective information concerning the NGRI plea in the literature, we find ourselves forced to agree with this position, but we hope that this deficiency will be rectified through systematized studies of the NGRI defense.

eudonursing: A Case of Galactorrhea

LEWIS M. COHEN, M.D., NED H. CASSEM, M.D., MARK E. MOLITCH, M.D., AND BRUCE J. BILLER, M.D.

Galactorrhea, or inappropriate lactation, has been cognized for centuries. Within the past decade, med-l investigators have reexamined this condition and lineated syndromes according to the presence or ab-nce of menstrual dysfunction and alterations of rum prolactin. Although prolactin secretion is regu-ed by the brain (1), and this hormone is known to luence behavior in lower animals (1), little is known out the psychological correlates and/or etiologic role emotional factors in galactorrhea. The following se report is prompted by the highlighting during ne-limited psychotherapy of the unique psycho-ysiologic aspects of galactorrhea. In contrast to the ore traditional psychosomatic diseases, this case of eudonursing, like those of pseudocyesis, proved to unusually responsive to a relatively superficial ex-oration of dynamics and underlying depression.

se Report

A 26-year-old woman was seen for seven sessions as part a comprehensive psychoendocrinologic evaluation of per-tent postpartum lactation. A planned and largely uneventful pregnancy had been followed by the delivery in October 1976 of a healthy first-born male child. Breast feeding was experienced as mutually pleasurable and was used to comfort and pacify dysphoric feelings in both mother and child. The patient continued to nurse despite her return, at 3 months postpartum, to her position as a pediatric radiology technician and an exhausting trip, 7 months postpartum, to her sister's university graduation. According to the patient's journal this trip marked the onset of a sexual dysfunction characterized by diminished libido, anorgasmia, and decreased coital frequency. At 10 months postpartum she developed uterine cramps, her intrauterine device was removed, she resumed oral contraception, and discontinued nursing. Her son had become at this point "a very independent child . . . so active that he broke his playpen . . . and seemed on the verge of weaning himself anyway." At 20 months postpartum, her galactorrhea persisted and she sought an endocrinologic evaluation. Her other complaints were the sexual disturbance, neurasthenia, and heightened irritability with her child and husband. Physical examination showed expressible milk in one breast, which did not decrease with a trial off of the oral contraceptives. The serum prolactin was normal (5.1 ng/ml). Formal visual field testing, sellaturcica polytomography, computerized tomography, and other pituitary and thyroid hormone levels were also normal. Psychiatric referral was made to investigate links between her physical condition and emotional life.

The patient had a brother 4 years older and a sister 6 years younger. She was the acknowledged favorite of her father, an alcoholic laborer, and the confidante of her mother. The mother, a chronically unhappy woman, was locked in a sexually impaired and vituperative relationship with her husband. Interestingly, she too had developed galactorrhea, which lasted for 20 years after the birth of the patient's sister.

0002-953X/79/02/0223/02/$00.35 © 1979 American Psychiatric Association

The patient spent a lonely childhood; she was afraid to invite friends over because of her parents' marital discord and her father's drinking. Despite intermittent periods of depression that began in high school, she excelled in her studies. She met her fiancé during a bout of depression in her sophomore year of college and married him following graduation. Until recently, their 5-year marriage had been a happy one, with a satisfactory sexual relationship and significant progress toward attaining financial security.

A short-term therapeutic contract was established. After the initial session she reported a dream in which a child, tethered to an I.V. bottle, accidentally jarred the pole. As it tottered and began to fall the patient desperately strove to catch it.

A poem she wrote 15 months postpartum contained the following thoughts:

I lie here in the dark
wondering if I can let him go

I gave up breast feeding him long
before I was ready to
That was the beginning
I miss the closeness, his
dependency on me

Every day now he's a little
less mine and a little more of
himself

It's sad to be a mother

In the second session she reported a lessening of her irritability. By the third session the flow of milk had diminished noticeably, and it disappeared totally by session 5. By session 6, she noted a return to her usual sexual functioning. Her generalized improvement continued through termination of this therapy and referral for long-term, insight-oriented therapy.

Discussion

This case recalls Helen Deutsch's observation that breast feeding cushions the impact of the physical separation that takes place at birth (2). The key unconscious conflict for this mother was the longing for reunion, the desire for separation and liberation, and the fear of losing everything. The exploration of these dynamic issues, manifested in the dream, poem, and associational material, led to a rapid resolution of her depression and symptom amelioration.

In the psychiatric literature abnormal lactation has been discussed chiefly in connection with pseudocyesis. In one review galactorrhea was present in 76 of 202 cases (3). Analytic case reports of patients with combined pregnancy delusions and galactorrhea also emphasize the paramount importance of separation/dependency issues, citing even premature termination of treatment as a potential precipitant (4, 5).

Galactorrhea occurs in 12%–46% of women of productive age, although fewer than 1% will be av of it and/or seek relief (6). Causes include pitui adenomas and neuroleptic medication, but the si largest category, typified by this patient, is idiopa galactorrhea with normal menses (7). Two-third these cases follow delivery and in 86% the basal lactin level is normal (7). The condition is endocr logically indistinguishable from that found with longed nursing. It has been postulated that the bre in these normoprolactinemic women are more se tive to prolactin, presumably due to an alteratio receptors (8). The present case suggests that this be corrected by psychotherapy.

Increasing information regarding the bioamine and peptidergic control of hypothalamic and pituit hormone secretion and the role of these substance brain function provides an opportunity to reexam the psychiatric and neuroendocrine aspects of same event (9). Since its isolation in 1970, prolac the phylogenetically oldest pituitary polypeptide h mone, has been demonstrated to play a significant in the premenstrual, pseudocyesis, and galactorr syndromes (1). Bromergocryptine, hypophysector and psychotherapy have all been associated with r malization of elevated serum prolactin levels (10), psychiatric evaluation and treatment should prove be of major importance in the future study of th complex psychopathophysiologic phenomena.

ychological Correlates of Preferences for Clitoral or Vaginal Stimulation

RONALD A. LATORRE, PH.D

A popular misconception is that Sigmund Freud was ponsible for positing two separate and distinct es of orgasms. For example, Offer and Simon (1) erred to "Freud's statement concerning the dif- ent kinds of orgasm," Sherfey (2) cited "the vaginal gasm as defined by Freud . . .," and Brecher and echer (3) stated, "Sigmund Freud presented, in ree Essays on the Theory of Sexuality, a theory that men can experience two kinds of orgasm—one cli- al, the other vaginal." However, Freud did not dis- ss either clitoral or vaginal *orgasms;* rather, he pro- sed that 1) in early childhood the female's chief togenic zone is the clitoris, 2) during puberty the male must adopt the vagina as the leading or domi- nt erotogenic zone, 3) fixation on clitoral preference presents childish masculinity (4–6), and 4) fixation clitoral preference may result in orgasmic dysfunc- ns (sexual anesthesia) during coitus (5, 7).

It is obvious, then, that Freud's thesis, which sug- sted a psychological basis for preferential stimula- n of the clitoris or vagina preceding orgasm, was torted by the assumption that there existed distinct ysiological correlates of such stimulation. When ch physiological distinctions were later disproven , Freud and his thesis received the misdirected ver- assaults. This is unfortunate, since there do exist finite psychological preferences for either clitoral or ginal stimulation as a precursor to orgasm (9, 10). rther, it is possible that these preferences are re- ed to important psychological differences.

This study is intended to provide some much- eded data in an area that is top-heavy with theory. accord with Freudian theory, I hypothesized that males who prefer clitoral stimulation are more mas- line or less feminine and that they experience fewer gasms during coitus than do those who prefer vagi- penetration. I also tested the following popular hy- theses: females who prefer clitoral stimulation 1) are re neurotic, 2) are less assertive, 3) have engaged re often in coitus, and 4) have had fewer and/or less joyable emotional and physical relationships.

The subjects were 306 nonvirgin unmarried women o volunteered to complete an anonymous, con- ential four-part questionnaire. Students were ap- ached in cafeterias and libraries. Nonstudents were solicited in medical hospitals (staff, patients, and visitors), a ski lodge, and three businesses located in different parts of the city. The sample included 187 college and university students (mean age=19.3 years) and 119 nonstudents (mean age=27.0 years). The nonstudent group included such professions as barmaid, freelance writer, hairdresser, librarian, model, private investigator, professional golfer, telephone operator, teacher, and tour coordinator. The most common occupations were secretary/typist/stenographer (16.9% of nonstudent sample), clerks (accounting, bank, or mail—16.8%), technicians (laboratory, medical, or research—9.2%), and nurses (5.9%).

Each volunteer completed a 5-item questionnaire regarding her sexual history, the Rathus Assertiveness Scale, the Eysenck Neuroticism Scale, and the McGill Gender Role Inventory.

The five sexual history items were as follows: 1) emotional relationship with opposite sex (none, unsatisfying, satisfying), 2) physical relationship with opposite sex (none, unsatisfying, satisfying), 3) sexual intercourse (never, occasionally with one person, frequently with one person, with more than one person), 4) coital orgasm (never, sometimes, frequently), and 5) most pleasurable part of lovemaking (clitoris stimulated by hand or mouth, penis within the vagina).

The Rathus Assertiveness Scale is a 30-item self-report inventory. The respondent indicates how characteristic each item is of her on a 6-point scale ranging from "very characteristic of me" (+3 points) to "very uncharacteristic of me" (−3 points). Nonassertive items are then subtracted from assertive items, so that positive scores reflect assertiveness and negative scores reflect nonassertiveness.

The Eysenck Neuroticism Scale is a 24-item self-descriptive checklist with yes-no answers. High scores reflect neuroticism.

The McGill Gender Role Inventory consists of 20 items. Each is rated on a 7-point scale ranging from "never or almost never true" (1 point) to "always or almost always true" (7 points). There are 10 masculine items and 10 feminine items, which are summed separately.

The sample was divided into those who preferred clitoral stimulation during lovemaking (99 students, 47 nonstudents) and those who preferred penile intromission (88 students, 72 nonstudents). Two-factor analyses of variance with unweighted means were used to analyze ordinal data. The two factors were sexual preference (clitoral, vaginal) and student status (student, nonstudent). The nonstudent group was significantly older than the student group, $F(1, 302)=193.7$, $p<.0001$, but the clitoral and vaginal pref-

data analysis was performed with the aid of the McGill Univer- Computing Centre and was supported by a McGill University ial Sciences Research Grant.

0002-953X/79/02/0225/02/$00.35 © 1979 American Psychiatric Association

erence groups did not differ in age and there was no significant Age×Student status interaction.

There were no significant effects or interactions for neuroticism or assertiveness. The students were more feminine (mean=45.1) than the nonstudents (mean =43.1), $F(1, 302)=6.98$, $p<.01$. Those who preferred clitoral stimulation tended to be more masculine (mean =43.4) than those who preferred vaginal stimulation (mean=41.7), $F(1, 302)=3.61$, $p<.06$.

Questions regarding sexual history were subjected to chi-square analyses with Yates' correction as necessary. More of the women in the clitoral preference group had never had an orgasm during coitus (18.5%), and fewer of them reported having frequent orgasms than those in the vaginal preference group (6.9% versus 46.5%), $\chi^2=9.58$, $p<.01$. When students and nonstudents were analyzed separately, more clitoral preference students reported never having orgasm during coitus (21.2% versus 8.0%), $\chi^2=6.45$, $p<.05$.

In addition, the ratio of vaginal to clitoral preference was larger in the nonstudent group, $\chi^2=5.27$, $p<.05$. It is difficult to interpret this finding precisely, but it could imply that vaginal preference develops with maturity, age, or coital experience. Since there was no relationship between amount of sexual experience and clitoral vs. vaginal preference, a maturational factor is more likely to be responsible, which would lend some support to Freud's transfer theory.

The results lend modest support to Freud's hypotheses that a woman who prefers clitoral stimulation to vaginal penetration tends to be more masculine and experiences fewer orgasms during coitus. However, one may explain the results in less pejorative terms than did Freud. For example, the reason that females who prefer clitoral stimulation attain fewer orgasms during coitus is not necessarily that they are obstinately clinging to childish masculine sexuality. It may very well be that women have less opportunity for direct clitoral stimulation in coitus, and those who pre such stimulation will be less satisfied and find orga more difficult to attain. Likewise, the masculinity a sociated with clitoral preference need not be regr sive. It may well represent a mature ability to ma one's preferences known despite contrary social pr sure. Although this assertiveness is more typica "masculine," it is now regarded by many as a mc mature response for the woman than it was in the pa The mechanism whereby such differences emerge mains to be more fully examined; however, the pr ent results do indicate that, despite physiological sir larities of orgasms produced by clitoral or vagi stimulation, there are psychological differences t tween those who prefer clitoral and those who pre vaginal stimulation.

Depression and Psychotic Regression Following Prolonged Methylphenidate Use and Withdrawal: Case Report

BY ALVIN A ROSENFELD, M.D.

Methylphenidate is used widely in treating minimal brain dysfunction. Remarkable symptomatic improvement is seen in some cases, while little effect is noted in others. Few adverse reactions have been reported (1, 2). There is debate over whether the drug caus growth retardation. There have been rare reports tics (3), psychotic episodes from initiation or abuse the medication (4), and choreoathetosis (5). The *Phy cians' Desk Reference* states that "careful supervisi is required during withdrawal, since severe depressi as well as the effects of chronic overactivity can unmasked." There are few reports of these sympto in the literature. Although depression following lo term amphetamine use is widely known, such a sy

rome has not been described with methylphenidate se in children.

ase Report

Allan A, a 9-year-old boy, was first evaluated because of epression, despondency, and suicidal ruminations. Allan ad been taking methylphenidate for over 3 years because of minimal brain dysfunction." His parents stated that with- it the medication Allan was "wild" and "uncontrollable," nning around the house, climbing trees, swinging from ings recklessly, and doing nonstop cartwheels in the family om.

Allan was the product of Mrs. A's first marriage. From rth, Allan seemed to be overactive, cried incessantly, and as "inconsolable." He was said to have celiac syndrome d several other allergies, but dietary change did not affect e situation. Mrs. A was anxious, upset, and depressed er her seeming inability to alleviate Allan's continual rest- ssness and crying.

When Allan was 2½, Mrs. A separated from his father, aving Allan with a relative for a few weeks. She later met d married Mr. A, a corporate executive.

When Allan was 5, Mr. and Mrs. A took him to a child ychiatrist for evaluation. The diagnosis was "hyperactive ndrome of childhood with psychoneurotic symptoms and rsonality traits." The hyperactivity diagnosis appears to ve been made on behavioral grounds, such as impulsivity d poor peer relationships at school. The psychoneurotic mptoms were said to be environmental.

After he was started on methylphenidate treatment, Al- n's behavior improved markedly. His mother felt that for e first time he was not uncontrollable. His school work mained excellent for the next several years, and his dis- ractability, impulsivity, and poor peer relationships im- oved. His IQ was in the very superior range, and he was an cellent athlete. His parents tried to stop the methyl- enidate on several occasions but noted each time that Al- n became uncontrollable.

When Allan was 8, Mr. and Mrs. A again requested a psy- iatric evaluation because Allan "hates himself and wants die." In addition, he was irritable, had frequent temper trums, and became inconsolable after even minor errors. lan was a very bright but depressed boy. He was sad, in- ibited, controlled, and somewhat suspicious in his play. Al- ough he wished to stop taking the methylphenidate be- use he felt it indicated there was something wrong with n, he also said he liked it because when he misbehaved, he uld always say he had forgotten to take his medication. ychological and neurological assessments were essentially rmal. Twice weekly psychotherapy was recommended to lp Allan with his depression, his poor self-esteem, and his fficulty getting close to classmates. Although the neurolo- st thought the methylphenidate was indicated by Allan's story, the psychiatrist decided that once an alliance had en formed with the family the methylphenidate should be ered and, if possible, stopped.

In the first months of therapy, Allan's play was inhibited d constricted, and he expended much effort to do things rfectly. He became overwhelmingly upset at the slightest ror. He insisted on competitive games but became ex- edingly frustrated and sulky if he lost. When anxious, he ached his genitals repetitively or rushed to the bathroom.

After 2 months of therapy, his parents stopped the methyl- enidate abruptly without consulting the physician. Allan remained in control for 7 days, but the next day became aggressive at school and punched another child. When seen in therapy that day, Allan was extremely overactive, ran from item to item, jumped on cabinets, and was unable to pay attention to anything for more than a few seconds. His speech was pressured and marked by frank paranoia. He felt his mother had numerous spies watching him at school and thought the therapist might also be a spy. Much of his play was exceedingly primitive. At one point, he formed an elongated piece of clay, placed it around his rectal area, and let it drop into a toilet as he laughed wildly. He then picked the clay up, placed it over his genital area, called it a penis, and had it break into little pieces, laughing in an uncontrollably anxious way. He was oriented, and no hallucinations were noted. It was thought that he was severely regressed and functioning at a psychotic level.

Allan was seen daily or every other day for the next week, and the therapist was in regular contact with Allan's parents. Over the next week, the psychosis slowly cleared. Although he was transiently more difficult to control, there was an added vivacity to his personality (his therapist noted that Allan had had a "zombie-like" quality previously).

With support, Allan's parents have been able to manage the home situation quite well and he has shown only mild behavior problems there. His school performance has continued to be excellent for the 10 months since methylphenidate was discontinued and he has made more friends. However, it is clear that he suffers from serious anxiety over issues of separation and loss. This anxiety is currently manifested at times of threatened loss by attention-seeking overactivity, "running away" games in therapy, sadism and guilt, and mild risk-taking. There has been no further depression or suicidal ideation.

Discussion

In this case, a severe depression was seen in an 8-year-old boy who had been given prolonged methylphenidate treatment. When the drug was withdrawn, a transient disorder of psychotic proportions appeared after 8 days, lasted about a week, and resolved spontaneously. This may be an isolated phenomenon or something others have seen but not yet reported. This case may suggest that the increased activity noted in some cases of methylphenidate discontinuation may result not from underlying minimal brain dysfunction or the unmasking of "chronic overactivity" but from a specific withdrawal phenomenon.

This case highlights the difficulty in making a diagnosis of hyperactivity. Further, it raises the possibility that the combination of an overwhelmed and depressed mother and a child with severe separation anxiety might lead to a mistaken diagnosis of "hyperactive child syndrome." Methylphenidate responsiveness may not be a good indicator of the difference between the correct and the mistaken diagnosis.

Tardive Dyskinesia and Antiparkinsonian Medication

BY GUY CHOUINARD, M.D., M.SC. (PHARMACOL), CLAUDE DE MONTIGNY, M.D., PH.D., AND LAWRENCE ANNABLE, B.SC., DIP. STAT.

Tardive dyskinesia, a neuroleptic-induced extrapyramidal hyperkinetic syndrome, is characterized by involuntary, repetitive, and purposeless movements that vary in localization and form. Common sites of involvement include the mouth, lips, tongue, and jaw, and, at times there are choreoathetoid movements of the neck, trunk or limbs (1). In a recent study of tardive dyskinesia in 261 schizophrenic outpatients undergoing long-term maintenance treatment with neuroleptics, we reported that 31% had tardive dyskinesia and that patients with tardive dyskinesia had fewer parkinsonian symptoms, particularly of the hypokinetic type, than those without tardive dyskinesia (2). These results suggest a balance between parkinsonian and dyskinetic symptoms. The present study was undertaken to investigate further the relationship between tardive dyskinesia and parkinsonism in schizophrenic patients receiving long-term maintenance treatment with neuroleptics. We examined the effects of the administration and subsequent withdrawal of the central anticholinergic (antiparkinsonian) agent procyclidine HCl on the extrapyramidal symptoms of 20 patients with significant tardive dyskinesia.

Method

Subjects. Twenty chronic schizophrenic patients (10 men and 10 women) were selected from the long-term wards of Hôpital Louis-H. Lafontaine, Montreal. Selection criteria required that patients 1) had received long-term maintenance neuroleptic treatment for at least 5 years, 2) had not taken antiparkinsonian drugs for at least 3 weeks before the study; and 3) had significant tardive dyskinesia (a score of at least 5 on a 9-point clinical global impression scale of tardive dyskinesia. All patients with physical illness, neurologic disease, alcoholism, epilepsy, or drug addiction were excluded from the study. All subjects completed the week trial (1 week with procyclidine and 1 week without procyclidine). The patients' ages ranged from 34 73 years (median=59), and their total length of hospitalization was 5.6–39.8 years (median=28.3).

Drug administration and assessment procedure. Patients were given procyclidine HCl (Kemadrin) 30 m day (10 mg t.i.d. in 5-mg tablets) for 1 week and the the drug was stopped for 1 week. All patients except were receiving neuroleptics at the time of the trial. T neuroleptic dose, which in chlorpromazine equivalen (3) ranged from 20 to 1850 mg/day (median =400 m mean=560 mg), was kept constant during the study p riod. One patient required a reduction (240 chlo promazine units) and 2 patients required increases (1 and 200 chlorpromazine units) in their maintenan neuroleptic medication during the trial, but for the p tients in question these were relatively minor change No other psychotropic drugs, hypnotics, or min tranquilizers were given during the trial. Patients we rated on Chouinard and Ross-Chouinard's extrapy midal symptom rating scale (ESRS) (4) before and a ter procyclidine treatment (days 0 and 8), and again week after withdrawal of procyclidine. The ESRS w completed independently by two psychiatrists (G. and C. de M.) during the same interview and a fir rating was made by consensus.

Results

Table 1 shows the mean scores for the ESRS befo and after 8 days of procyclidine treatment. Me scores at day 8 were compared with those at day using the paired t test. Procyclidine treatment led to significant decrease in the mean total score for parki sonism (excluding nonacute dystonia). Howeve there were significant increases in the mean scores f dyskinesia of the jaw and other involuntary dyskine movements and a tendency toward higher total scor for tardive dyskinesia. There was a negative correl tion that approached significance ($r=-.45$, $p=.06$) b tween the changes in total scores for parkinsoni symptoms and dyskinetic movements, indicating th patients with increased scores for dyskinetic mov

ents tended to have decreased scores for parkinson-m. One week following withdrawal of procyclidine a rther evaluation of these patients revealed that the ean total scores for parkinsonism and dyskinetic ovements had returned to baseline levels (scores of 6 and 14.5, respectively). A random sample of 10 of ese patients assigned to placebo in a study com-ring deanol and placebo was reevaluated 1 month ter withdrawal of the antiparkinsonian, and the ex-apyramidal symptoms remained stable at baseline vels.

scussion

The present study shows that the central anti-olinergic agent procyclidine had an effect on tardive skinesia opposite to that on parkinsonism, improv-g the latter but exacerbating the dyskinetic move-nts. These findings, which are in agreement with re-rts by Fann and Lake (5) and De Fraitas and associ-es (6), are consistent with the dopamine super-nsitivity hypothesis of tardive dyskinesia (7). Indeed, ocyclidine may have excerbated dyskinetic symp-ns by its dopamine reuptake blocking property and/or its central anticholinergic activity, thus ex-gerating a dopaminergic-cholinergic imbalance (9). s there is evidence that early signs of tardive dyski-sia may be reversible (10), uncovering the syndrome use of a central anticholinergic (antiparkinsonian) ug may aid in its early detection and prevention. The esent study demonstrates that the exacerbation of dive dyskinesia by the short-term administration of ticholinergic drugs is readily reversible, so the pro-dure does not appear to be harmful to the patient.

We have observed that the hypokinetic parkinsonian symptoms of rigidity and akinesia often act to reduce or cover the expression of dyskinesia (2). By alleviating hypokinetic symptoms, central anticholinergic drugs could help to prevent the masking of tardive dyskinesia by neuroleptic-induced hypokinesia. Early discovery of tardive dyskinesia in this way might lead to its reversal by means of a timely reduction in antipsychotic dosage. On the other hand, it is possible that the hyperkinetic parkinsonian symptoms of tremor (especially pill-rolling) and akathisia are precursors of hyperkinetic symptoms of dyskinesia (2). Hyperkinetic parkinsonism may coexist with dyskinetic movements in patients who are at the stage when their symptoms are progressing from one syndrome to the other. One way to avert the development of severe tardive dyskinesia may be to prevent patients from developing severe hyperkinetic parkinsonian symptoms by reducing their neuroleptic dosage at the first signs of hyperkinesia. We therefore propose that uncovering tardive dyskinesia by short-term administration of an antiparkinsonian may aid in early detection and help to prevent the subsequent development of incapacitating forms of the disorder.

Alleviation of Manic Symptoms with Catecholamine Agonists

BY WALTER ARMIN BROWN, M.D., AND BARBARA MUELLER

In its simplest form the catecholamine hypothesis of affective disorder postulates that depression is associated with a functional depletion of catecholamines at central synapses and mania with a functional excess. Accordingly, the following pharmacologic agents might be expected to increase the severity of mania: L-dopa, which increases brain levels of catecholamines; apomorphine, which stimulates postsynaptic dopamine receptors; and methylphenidate and *d*-amphetamine, which release and block the reuptake of catecholamines. However, in the course of a study involving these drugs the two patients who received them during a manic episode experienced transient alleviation of manic symptoms.

Observations

Two physically healthy men, aged 54 and 46, with well-documented histories of mania and depression participated in a neuroendocrine research study for which they had given informed consent. They had been taking no medications other than lithium. Within 1 week after a double-blind switch from lithium to placebo they became manic, with marked hyperactivity, pressured speech, and elated, irritable, labile mood (episodes similar to those they had experienced in the past). They were the only subjects in the study who became manic after the switch to placebo.

After they had been given placebo for 10 days they received L-dopa (500 mg p.o.), apomorphine (0.5 mg s.c.), methylphenidate (20 mg p.o.), and *d*-amphetamine (15 mg p.o.) in a random sequence on a double-blind basis. Each drug was given at 10:00 a.m. on a different day following an overnight fast. Patients were observed continuously during the hour before and 2 hours after drug administration and intermittently during the rest of the day.

Neither patient showed an increase in mania after the administration of any of these drugs. In fact, about 45 minutes after the administration of each drug, the patients' rates of speech and gross body movement approached normal levels, and their comments indicated that they felt more relaxed. These effects lasted for about 3 hours, after which the full-blown manic syndrome recurred. About 45 minutes after administratic of each drug one patient dozed intermittently for 3 minutes. *d*-Amphetamine seemed to be more effecti than the other drugs in alleviating manic symptoms.

Discussion

These observations are entirely consistent with th only other study we know of in which *d*-amphetamii was administered to manic patients. Beckmann ar Heinemann (1) gave *d*-amphetamine (30–50 mg I.V.) six manic patients. They assessed the patients by usi the Beigel-Murphy scale before *d*-amphetamine i fusion and at 30, 90, 150, and 270 minutes after i fusion. All six patients experienced suppression their manic symptoms, and three of them showed tendency to fall asleep. These changes were reflect in their mania scores, which showed a significant d crease 30 minutes after infusion. Their scores i creased thereafter, reaching initial values appro mately 3 hours after infusion. These authors point out that *d*-amphetamine significantly reduced euphoi symptoms but not aggressive symptoms. A placebo fect has not been definitively ruled out in either o study or the one of Beckmann and Heinemann, but t temporal pattern of alleviation and recurrence symptoms is consistent with the pharmacodynamics these drugs. These data in the aggregate indicate th mania is certainly not worsened and is likely to transiently alleviated by *d*-amphetamine.

Janowsky and associates (2) observed mixed clinic changes following intravenous infusion of meth phenidate (0.5 mg/kg) to 10 acutely manic patients. Dopa has been shown to induce hypomania in so bipolar manic-depressive patients, and *d*-amphetami and piribedil (a dopamine receptor stimulating age have been shown to induce mania rarely in such p tients (3, 4). These findings and those we have repo ed are difficult to reconcile with current thinking (i. the catecholamine hypothesis) on the pathophysiolo of mania. Although reduction of mania following l doses of dopamine receptor agonists might be accou ed for on the basis of presynaptic inhibition, such mechanism cannot account for the antimanic effe we have noted with L-dopa and methylphenidate a we and others have noted with *d*-amphetamine. Phy stigmine, a central cholinesterase inhibitor, has a been found to alleviate manic symptoms (5). Do mine agonists have been shown to have anticholiner effects, so it is not likely that the results we have no are mediated through increased cholinergic activ (6). However, in view of data suggesting that cholin gic stimulation can activate catecholamine systems

ıd of the findings suggesting that catecholamine gonists reduce mania, it is possible that the effects of ıysostigmine on mania are mediated by central cate-ıolamine pathways.

The fact that L-dopa and tricyclic antidepressants ın precipitate mania in some bipolar manic-depres-ve patients is certainly consistent with the hypothe-s that an "excess" of catecholamines at central syn-ses can have some role in inducing mania. These ıta, however, along with ours and those of Beck-ann and Heinemann showing rapid transient alleviа-ın of manic symptoms with *d*-amphetamine, would em to indicate that the induction, maintenance, and eviation of mania involve different and complex uronal processes that are not limited to shifts in the ailability of catecholamines at central synapses. hile other investigators have pointed to clinical, armacologic, and physiologic observations in af-ctive disorder that cannot be accounted for by the techolamine hypothesis (7), this hypothesis contin-s to dominate and possibly restrict our thinking. Al-ough it has had great heuristic value and demon-rated usefulness, slavish acceptance of the cate-olamine hypothesis in the absence of confirmatory ta can limit further progress in our understanding of affective disorders and impede the development of novel effective treatments.

The rapidity of the response to catecholamine agonists noted in this and the Beckmann and Heinemann study suggests the possible usefulness of these drugs in the treatment of mania.

edical Histories of Psychiatrically Referred Delinquent Children: An Epidemiologic udy

DOROTHY OTNOW LEWIS, M.D., AND SHELLEY S. SHANOK, M.P.H.

The purpose of this paper is to report differences tween the medical histories of a group of delinquent ildren recognized by court personnel as requiring ychiatric evaluation and the medical histories of eir nonreferred court-involved peers. In a previous per (1), we reported that a random sample of delin-ent children known to the juvenile court had signifi-ntly more numerous and serious medical problems an a matched sample of their nondelinquent peers. that study, we chose to compare non-psychiatrical-referred delinquents with nondelinquents to avoid ewing our findings toward pathology. We wondered, wever, whether objectively ascertainable differ-ces existed between the medical histories of two oups of delinquent children, one referred for psychiatric evaluation and one never referred. If there are significant differences that indicate specific vulnerabilities in psychiatrically referred delinquents, the greater professional attention given the referred group would be justified. A finding of no significant differences between the groups would suggest that psychiatric referral was a chance happening and that most court-related children, psychiatrically referred or not, require professional attention.

We have previously reviewed the current literature on the medical status of delinquent children (1). To summarize, while some investigators have reported an association between perinatal and/or neurologic disorders and subsequent maladaptation (2–7), others have found little if any relationship between ill health and delinquency (8, 9).

Method

A consecutive sample of 65 delinquent children referred to a court clinic for psychiatric evaluation in the early 1970s was matched for age, sex, race, geographic area, and, as far as could be ascertained, socioeconomic status with a sample of 65 non-psychiatrically

Parental psychiatric treatment	22	33.8	10	15.4	5.969	.01

*Percentages are based on the actual numbers of subjects for whom information was available.

referred children known to the juvenile court during the same period of time. One-third of the subjects in both groups were girls; 44% were black and 56% white. The average number of offenses was 10.5 for clinic-referred children and 2.92 for non-referred children ($t=2.34$, $p=.02$). Thus the clinic-referred children were significantly more delinquent than the nonreferred children. They tended to have committed more serious offenses (i.e., offenses against persons) and to be younger at the time of their first offense.

Medical histories were evaluated by reviewing hospital records from the main general hospital serving the area. The choice of this data source and its limitations and advantages have been discussed in detail previously (1, 2). As in our previous studies, records were assessed in terms of numbers of hospital contacts, reasons for contacts (e.g., accidents, illnesses), and timing of medical events.

In a previous study, the prevalence of past or present psychiatric treatment in state facilities of the parents of delinquents was obtained (10). These objective data on parental mental health were also used in the present study.

Results

Psychiatrically referred delinquents did not differ significantly from their nonreferred peers in terms of numbers of hospital contacts. Both groups made frequent use of all services.

As can be seen in table 1, a significantly greater proportion of psychiatrically referred delinquent children had experienced perinatal difficulties, child abuse, and injuries, specifically head and face injuries, through age 16. The severity of injuries is indicated by the greater proportion of referred children who had received EEGs and skull X rays. Furthermore, a greater proportion was recognized as having seizure disorders. Differences between the two groups were evident by age 2 years.

It is noteworthy that a significantly greater proportion of psychiatrically referred children had a parent known to have received psychiatric treatment at one of the major state facilities serving the area (33.8% versus 15.4%).

Discussion

Our previous epidemiologic studies indicated th delinquents as a group suffered from more adve medical histories than their nondelinquent peers. T present study shows that those delinquents referred a psychiatric clinic affiliated with a juvenile court h even more serious medical histories than did their n referred peers.

The nature of the problems found in the clinic- ferred group is of special importance. These child were significantly more likely than the nonrefer group to have experienced perinatal difficulties, ph ical abuse, and head and face injuries. Furtherm many of the clinic-referred group of delinquents h experienced documented head and face injuries dur early life, with significant differences noted by ag years. The parents of clinic-referred delinquents w a more psychiatrically disturbed population than parents of nonreferred delinquents.

These findings have special implications for all cl cians evaluating children for court purposes. It wo seem that referral by probation staff for psychia evaluation is not a random happening. Those de quent children for whom evaluations are sought t to come from the most psychiatrically disturbed fa lies and to have experienced the greatest amount early CNS trauma, including perinatal difficult head and face injuries, and child abuse. The delinqu child referred for psychiatric evaluation is, therefo especially likely to be both psychologically and ph ically vulnerable to maladaptation if appropriate di nosis and treatment are not initiated.

ardiovascular Safety of Rapid Treatment with Intramuscular Haloperidol

Y PATRICK T. DONLON, M.D., JOHN HOPKIN, M.D., CHARLES B. SCHAFFER, M.D.,
ND EZRA AMSTERDAM, M.D.

Haloperidol and other neuroleptics administered intramuscularly at close intervals can provide rapid control of the severe symptoms of acute psychotic decompensation (1–5). How safe is the procedure? In this study we investigated the effects of rapid treatment with intramuscular haloperidol on heart rate and blood pressure in acutely psychotic patients.

Method

The subjects of this study were 25 recently hospitalized schizophrenic adults (16 men, 9 women) in good physical health. The patients' mean age was 26 years. Approximately three-fourths of them (N=19) had had symptoms of schizophrenia for less than 3 months, the remainder for somewhat longer. Written permission for treatment in the study was obtained from the patients after they were informed of the risks and possible benefits.

Each patient was assessed clinically and psychometrically. Patients were then given an intramuscular injection of haloperidol, 2.5 to 10 mg, depending on the severity of symptoms. Injections were repeated every 0 minutes if necessary after the therapeutic response nd vital signs were evaluated. Vital signs were recorded before treatment and every 30 minutes for 6 ours following the first injection. Cardiac function as monitored closely in 6 of the patients by means of he Holter monitor. Laboratory tests conducted before nd after treatment included complete blood counts, MA-12 analysis, serum electrolytes, urinalysis, and etermination of values for serum creatinine phoshokinase (CPK).

eceived Aug. 25, 1978; accepted Nov. 8, 1978.

r. Donlon is Associate Clinical Professor, Department of Psychiay, School of Medicine, University of California, Davis, 3340 V St., acramento, Calif. 95187, where Dr. Hopkin is Assistant Clinical rofessor and Dr. Amsterdam is Associate Professor, Section of ardiology, Department of Internal Medicine. Dr. Schaffer is Reearch Associate, Illinois State Psychiatric Institute, Chicago, Ill.

Results

During the 6-hour study period, the mean total dose of haloperidol administered to the patients was 22.5 mg (range=10–40 mg). Of the total of 145 injections given, 65 were 2.5 mg, 72 were 5 mg, 6 were 7.5 mg, and 2 were 10 mg. All patients completed the study.

Analysis of variance indicated that there were no significant reductions in mean values for blood pressure and pulse rate; both decreased gradually within the normal range (table 1). These decreases paralleled the calming effects of haloperidol and its control of core symptoms of psychosis, including thought disturbance. (We plan to write a separate report on therapeutic results in this study.)

Only one patient, a 36-year-old woman who weighed 54.5 kg, had a clinically significant blood pressure decrease. Her blood pressure decreased from a pretreatment value of 100/60 mm Hg to 90/50 mm Hg after she received the first dose of haloperidol, 5 mg I.M. It then decreased to 80/50 mm Hg after a second injection of 5 mg was given 30 minutes later to control severe symptoms. Pulse rates in this patient were 80 beats per minute (bpm) before treatment and 72 bpm after both injections. Although she did not have symptoms of hypotension, parenteral treatment was stopped to avoid further decrease in blood pressure. Her blood pressure returned to pretreatment levels approximately 6 hours after the initial injection.

Holter monitor recordings indicated abnormal heart rates with sinus arrythmia in 2 of the 6 patients. In both cases, the cardiac abnormalities were present at baseline recordings and did not worsen during treatment. One of these patients had sinus arrythmia and an episode of syncope and was subsequently diagnosed as having mitral valve prolapse. Because such phenomena are part of the symptomatology of mitral valve prolapse, the role of haloperidol in this case, if any, is not clear. The patient, a 24-year-old man weighing 70.4 kg, had a grade III/VI systolic murmur before treat-

ment but had been allowed to participate in the study after his case was reviewed by a cardiologist. The patient had a brief episode of syncope about 3½ hours into the treatment period after he had received a total of 37.5 mg of haloperidol. Blood pressure and pulse rate, taken immediately, were 164/74 mm Hg and 60 bpm. The patient did not lose consciousness completely, and his subsequent clinical course was uneventful. The Holter monitor recording for this patient indicated sinus arrythmia with abrupt changes in heart rate; syncope was preceded by tachycardia (130 bpm) that shifted rapidly to bradycardia (50–55 bpm). These changes in heart rate, however, were similar to other changes that occurred before as well as during his haloperidol treatment. The diagnosis of mitral valve prolapse was established by echocardiogram the day after the episode of syncope.

The second patient with abnormal Holter monitor recordings was also a 24-year-old who had abrupt changes in heart rate, e.g., 83 to 45 bpm in 2 beats. He had also had sinus arrythmia before treatment with haloperidol, and it did not worsen.

Holter monitor recordings in the other four patients were unremarkable. Results of laboratory tests were also unremarkable. Values for CPK were characteristically elevated before treatment because the patients were psychotic (6). These values were elevated further (300–2541 IU) by the trauma of intramuscular injection.

Comment

The results of this study indicate a high degree of cardiovascular safety for healthy subjects who require treatment with moderate doses of haloperidol at 30-minute intervals for the control of the symptoms of acute psychosis. Nevertheless, it is prudent to assume that the risk of cardiovascular effects during rapid treatment with neuroleptics may be greater in elderly psychotic patients and all patients who are medically ill, particularly with cardiovascular disease. Patients in these categories should be treated with small doses of haloperidol and monitored closely throughout rapid treatment with neuroleptics. Idiosyncratic reaction to haloperidol and other neuroleptics is also a possibility for any patient.

ETTERS TO THE EDITOR

is section contains reactions to Journal *articles, statements of opinion, comments on Association activities, quests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions garding publication. Letters must be typed double spaced throughout and should not contain more than 500 rds and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for sponse. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform iters of the disposition of letters or return those which are not printed.*

P: Neurochemistry, Treatment, and More

SIR: We would like to comment on "Phencyclidine-Induced chosis" by R. Michael Allen, M.D., and Steven J. Young D. (September 1978 issue). First, our clinical experience pports their conclusion that phencyclidine (PCP) produces linical picture that is closer to that of schizophrenia than es amphetamine. If this is correct, then understanding the rochemical basis of the effects of PCP is of considerable portance. We would like to elaborate on the personal comnication the authors cited from us, which indicates that effects of PCP may be due in part to its actions on dopae metabolism, and to suggest that reserpine, which cks dopamine storage, and/or α-methyl-*p*-tyrosine MPT), an inhibitor of dopamine synthesis, should be tried he treatment of prolonged psychotic reactions from PCP.

The effects of PCP on dopamine-dependent behaviors in s are mediated by presynaptic effects on dopamine neus rather than effects on postsynaptic dopamine receptors. us, PCP causes ipsilateral turning in rats with 6-hydroxypamine-induced lesions of the substantia nigra (unpubhed data from Fessler, Sturgeon, and Meltzer). Its effects dopamine metabolites are blocked by γ-hydroxyyrolactone, an anesthetic that inhibits the firing of dopae neurons (1). We have found that the effects of PCP on omotor activity and stereotypy are almost completely inited by reserpine treatment; in contrast, amphetamine's ects on locomotor activity are potentiated by reserpine treatment. This indicates the effects of PCP are mediated part by storage pool dopamine that is depleted by reserne. We have also found that the effects of PCP on turning havior in the rat are inhibited by pretreatment with MPT, which indicates that some actions of PCP may also pend upon release of newly synthesized dopamine. Finalwe have evidence that PCP can block dopamine uptake in ro.

This multiplicity of effects of PCP on dopamine may conbute to the diverse effects of PCP on behavior compared h amphetamine, whose actions on dopamine appear to be ited to release of newly synthesized dopamine and blocke of dopamine uptake. It is tempting to conclude that store pool dopamine may have more relevance to behavior an has previously been appreciated. Since both drugs afct other neurotransmitter systems, however, we are not pposing a simple relationship between dopamine and psypathology.

We would nevertheless urge clinical treatment with reserne, which is clinically available, or AMPT, which is available for clinical investigations, or with both, for individuals with prolonged schizophreniform psychoses following PCP use. This might prove more effective than using dopamine receptor blockers such as haloperidol, since such drugs increase the activity of dopaminergic neurons by negative feedback from postsynaptic dopamine receptors as well as presynaptic mechanisms. Increased presynaptic activity could overcome the effect of the neuroleptics.

SIR: We were very interested in the article by Drs. Allen and Young on phencyclidine-induced psychosis. We have recently completed a study of 15 patients with PCP psychosis and we obtained similar data, which indicated that it is difficult, if not impossible, to separate PCP psychosis from schizophrenia on clinical grounds (1). However, we disagree with the authors on a number of other points.

First, the fact that it is difficult to separate two diseases on clinical grounds does not make one a model for the other. There are basic differences in the phenomenology of the two processes: 1) PCP psychosis has an inherent component of sensory deprivation due to the anesthetic properties of the drug, which are lacking in schizophrenia, and 2) in our experience, PCP psychosis has a strong component of cognitive impairment, the clearing of which is our criterion for discharge, while the cognitive impairment in schizophrenia is classically less important. Nevertheless, we have found one intriguing parallel component in the two processes: temporal disorganization. Based on work by Melges, we studied temporal disorganization (impairment of time sense) in PCP psychosis and found preliminary evidence that on at least one test of temporal disorganization (estimating a period of 30 seconds) PCP users consistently underestimate, as do schizophrenics. The implications of such findings have been discussed elsewhere (2).

Second, we disagree with the authors on psychopharmacologic management. A clear distinction should be made between acute and chronic patients. We have always used diazepam to sedate our acute patients because of several reports of cardiac arrhythmias and hypotension in acute PCP patients treated with antipsychotics (1, 3, 4). Not all clinicians will agree with this treatment, and the treating psychiatrist will be under considerable pressure from the nursing staff to "control" these potentially violent patients, but we have seen one case of the interaction (with haloperidol) and would caution against it. Seclusion and restraint should also be used with caution; we have had one patient who developed acute renal failure secondary to acute rhabdomyolysis (tearing of muscles and release of myogloben) due to prolonged restraint. On the other hand, we have no reservations about the use of antipsychotics in PCP patients who are suffering the chronic effects of abusing the drug or in subacute cases once there is no free drug in the serum. Thus, we would advise caution in the acute treatment of these patients and encourage the initial use of diazepam in doses of up to 60 mg/day rather than antipsychotics.

Drs. Allen and Young Reply

SIR: Athough we are sensitive to the points made by Drs. Yesavage and Freeman, we feel we can answer them satisfactorily.

As to their first criticism of our proposing prolonged phencyclidine-induced psychosis as a good model for schizophrenia, we can only reiterate our position that in our study PCP produced a clearer, longer lasting schizophreniform illness than other previously reported drug models. As to the drug model concept of schizophrenia itself, the amphetamine model of schizophrenia proposed by Snyder and the psychedelic model summarized by Wyatt (1) have been generally accepted as conceptually useful in the study of schizophrenia. Recent work with PCP indicates that it fits both the dopamine hypothesis of schizophrenia (2) and the dopamine-acetylcholine balance hypothesis (3) of schizophrenia quite well. Garey and Heath (4) demonstrated that PCP inhibits the reuptake of dopamine in rat striatal synaptosome preparations, and Finnegan and associates (5) demonstrated that PCP has both potent dopaminergic and anticholinergic activity. Thus our clinical data fit quite well with the recent neurochemical data.

As to their criticism of our psychopharmacological management of our patient sample, we can only say that there are no significant differences between our views. We stated in our report that none of our patients was acutely intoxicated with PCP. Our patients were all subacute and chronic in their presentation. None had acute neurologic signs and none had ingested PCP less than 8 hours before hospitalization. Unfortunately, we did not have the facilities to monitor blood PCP levels in our patients. We agree that for acute PCP intoxication diazepam is the treatment of choice and physical restraint should be minimized and good nursing care maximized. We were discussing our treatment of behaviorally disordered patients following their acute toxic phase, and we found that although neuroleptic treatment was not extremely effective in reducing psychotic thought processes, it was helpful in preventing dangerous agitation or destructive behavior.

SIR: The emergence of phencyclidine (PCP) as a ubiquitous drug of abuse has become a matter of concern. The intensity of behavioral disruption PCP produces in humans seems to surpass that of all other drugs of abuse. No antagonist is now available to combat the behavioral effects of acute PCP intoxication. Therefore, the recent finding in the laboratory that baclofen is effective in antagonizing the psychomotor effects of PCP in experimental animals is of interest.

Phencyclidine produced intense locomotor stimulation in Swiss mice that was characterized by compulsive running activity. This effect was completely blocked by baclofen, administered before PCP or at a time when the effect of PCP was maximal. In albino rats, the characteristic head-sways produced by phencyclidine was effectively antagonized by baclofen. In both of these experiments, the impressive blocking effect of baclofen started within 5 minutes after intraperitoneal administration and lasted for 60–90 minutes with no return of the PCP-induced symptoms. However, baclofen failed to influence *d*-amphetamine-induced locomotor stimulation. Diazepam, currently used in the management of PCP intoxication, was ineffective in these tests. Details of the pharmacologic and biochemical studies will be published elsewhere.

Baclofen, a putative γ-aminobutyric acid (GABA) agonist (1, 2), has been found useful in the treatment of spastic disorders (3). It also has been reported to produce beneficial effects in Huntington's chorea (4) and tardive dyskinesia

l has been found to be a safe drug. Other properties of this ıg, such as its muscle relaxant and anticonvulsant effects l sedation also could prove to be beneficial in the manage- nt of acute phencyclidine intoxication. Whether baclofen ɔ blocks the psychopathologic effects of PCP in man has be investigated, and efforts to perform such studies in this spital have been initiated.

ıtelet MAO Research: Complications

SIR: Arnold J. Friedhoff, M.D., and associates are to be nmended for their excellent discussion of the comxities involved in interpreting human blood platelet bio-ɜmical results (August 1978 issue, pp. 952–955). The au-ɾrs are correct to point out that platelets represent a heter-ɜneous population; in fact, new platelets produced under ıditions of increased demands are larger than average and ◂ain large throughout their life span (1). Ordinarily, plate-ɜ become smaller with age, and physiologic differences ɹe been found among platelet populations of varying sizes . To complicate matters further, platelets stay in the circu-ɾon 7–14 days and may be removed either randomly or ectively with aging (3). Thus, any biochemical platelet ɜasure is an average of a heterogeneous population sam-ɔd at a particular time in an ever-changing production-de-■uction equilibrium.

The blood platelet is an organized, but dying, fragment of ɜgakaryocyte cytoplasm and, as such, is totally dependent ɔn the megakaryocyte for its integrity. By the time one nples a platelet population, a series of critical steps have ◂eady occurred in the megakaryocyte population. Interingly, megakaryocytes produce platelets after replicating ɜir chromosome complement a variable number of times, l the amount of platelet-producing cytoplasm apparently ɾelates with the chromosome complement (4). For exple, platelets are probably produced from megakaryoɜes varying in ploidy values from 4N to 64N (where ɜone haploid chromosome complement) (5). This raises ne interesting questions about the quality and quantity of nsfer of genetic material to the platelet population, per-■ps adding to the heterogeneity. Thus, although platelet AO levels are genetically determined, the amount found at ɣ one time may be dependent on the chromosome comɜment of the megakaryocyte population from which the ■telets were derived. Furthermore, since psychoactive ıgs can affect leukocyte and erythrocyte production, one has to wonder whether certain megakaryocyte parameters may also be affected in certain instances, since these three types of blood elements originate from the same stem cell line (the pluripotential stem cell) (1, 3).

The purpose of this letter is not to discourage the use of platelets in schizophrenic research but to agree with the authors and to point out further complexities in the use of the platelet model in psychiatric research. Research in the areas discussed above may lead to a better understanding of seemingly contradictory laboratory results.

Considering Lethal Catatonia in Cases of Hyperpyrexia

SIR: Two recent articles in the *Journal* (1, 2) have presented cogent facts and arguments implicating phenothiazines as a contributory cause of hyperpyrexia in the mentally ill, an association first suggested by Ayd (3). It is important to keep in mind that hyperpyrexia in the mentally ill may be due not to the medications the patient is taking but to a mysterious illness known as lethal catatonia. The syndrome was first reported by Luther Bell in 1849, more than a century before there were any phenothiazines. Hyperpyrexia has been noted in about a third of the patients with lethal catatonia (4). We need to be careful to avoid automatically attributing a patient's hyperpyrexia to medication.

Freud and Religion

SIR: I wish to point out an error in "Report of the Task Force on Religion and Psychiatry: Phase III" (June 1978 issue, Official Actions). The remark attributed to Freud, "And now you must not be surprised if I plead on behalf of retaining the religious doctrinal system as the basis of education

and of man's communal life . . . ," is actually that of Freud's fictional antagonist in "The Future of an Illusion" (1). Throughout this work Freud erected this pro-religion straw man, only to demolish him.

However, this is less of an error than it appears—and in fact becomes a sort of truth—if we choose to read the fictive opponent's comments as the unconscious opinion of Freud himself. There is ample documentation of Freud's mixed feelings on the subject. In the very work in which he declared religion a "universal obsessional neurosis" (2) Freud opined that "a progressive renunciation of constitutional instincts [which he considered one of the foundations of social cohesion] is effected by religions, in that they require the individual to sacrifice his instinctual pleasure to the Diety." This was repeated in 1908. Only a few months before he suggested in "Leonardo da Vinci" that religion may be a determinant of neurosis, he had written Pfister regarding "the happy state of earlier times when religious faith stifled the neuroses" (3, p. 16). In a 1919 addendum to "Leonardo" and in *Group Psychology and the Analysis of the Ego* he reiterated this. Although on balance "The Future of an Illusion" and "Civilization and Its Discontents" are unfriendly toward religion, "Moses and Monotheism" contains a much softer view.

Many pages could be written about the determinants—some of which are noncognitive and unconscious—of Freud's ambivalence. I think these include 1) conflicts over aggression and competitiveness vis-à-vis the father, 2) dependency-independence conflicts vis-à-vis the mother and, to a lesser extent, the father, 3) unresolved feelings on the issue of mortality-immortality, including Freud's search for meaning in life, 4) contact with the repressive and hypocritical religion and mores of fin de siècle Vienna and their repercussions on his patients, 5) Freud's ambivalence toward his Jewishness, and 6) the dichotomy between rationalistic-positivistic and romantic elements in Freud's education manifested partly by his lifelong battle with his speculative or "mystical" tendencies (4).

Although an ocean of ink has been spilled on the topic of religion and psychoanalysis, there is still great controversy about the compatibility of the two. Part of the problem is that the philosophical and ethical implications of psychoanalysis have not been fully worked out. The questioning, reductionistic attitude of dynamic psychology seems quite foreign to the faith-enjoining modus of religion. In considering such questions, it may be wise to keep in mind what Freud said in 1927:

> In point of fact psycho-analysis is a method of research, an impartial instrument, like the infinitesimal calculus, as it were. . . . If the application of the psychoanalytic method makes it possible to find a new argument against the truths of religion, *tant pis* for religion; but defenders of religion will by the same right make use of psychoanalysis in order to give full value to the affective significance of religious doctrines. (1, p. 127)

A Comment on Runaway Houses

SIR: I am writing in regard to "The Runaway Center a Community Mental Health Center" by James S. Gord M.D. (August 1978 issue). It is quite true that runav houses provide a most needed service. Many disenchar youth see the traditional physician's office as "est lishment" and therefore to be shunned. Going to a runav house instead enables them to avoid being seen as psych ric patients and also serves as a diversion from the path leads to juvenile court. At times, a few days away from family plus supportive counseling will help the young per reenter school and family. The runaway center also ke the teenager from living on the streets and turning to dru prostitution, and other antisocial behaviors.

It would appear that runaway houses are the answers today's youth. Unfortunately, their appeal is also a g source of weakness. The staffs of such centers are o poorly trained or untrained. Psychopathology often goes noticed until it erupts into a full-blown psychotic episc With relatively poor diagnosis and treatment regimens, sociopathic teenager is able to find a place where he or can take full advantage of the other adolescents.

Techniques of family therapy are sophisticated eno today for effective intervention if there is continuing tr ment. However, the expertise for such treatment is o found in the traditional agencies such as the commu mental health center.

Everyone who works with young people realizes tha number of different agencies have contact with the sa type of problems. Physicians, psychiatrists, mental he centers, hospitals, juvenile courts, and runaway houses see troubled young people. Each staff has a different philo phy and level of training. If one agency could coordir with another, it is probable that each agency would be be able to serve the needs of this group and the service wo be more cost effective. There is a need for both levels service but an even greater need for communication and operation between services.

PAUL KING, M.D.
Memphis, Tenn.

Dr. Gordon Replies

SIR: Dr. King's introductory paragraph emphasizes importance of runaway centers in diverting young pec from incarceration in mental or penal institutions and helping young people who cannot or do not want to surv on the streets. His final paragraph correctly highlights importance of cooperation among the staff of runa houses and other mental health, social service, and juve justice agencies. However, in between, Dr. King make number of damning and unsubstantiated statements at the staff of runaway houses, the services offered to yo people who come to them, and the success of family ther in working with young people who stay at home.

Although family therapy might indeed help young pec

live happily at home, it has generally been unavailable or, delivered by many mental health professionals, unacceptle to young people who have left or are about to leave their mes. Therapists may speak of "family problems," but ung people often feel the therapists share the parents' int of view and biases. In any case, when things get rough, e young people are the ones who have to take the psychogical tests or enter the mental hospitals.

The runaway house provides a context in which family erapy takes on a different meaning. When offered by counlors who have proved themselves empathic and trustorthy, by a staff that eschews labeling, diagnosis, institunalization, and medication, family therapy is regarded by ung people as a catalyst to productive change, not an inrument of parental domination. I noted in my article that most half of all the young people who come to stay at runay centers are involved in family therapy and that onearter of the clients of runaway houses continue to live in eir own homes while they receive individual and family unseling.

Dr. King's indictment of the training of runaway house unselors is unfair. I noted in my article that over the last ur to five years runaway centers have "made use of ineasing numbers of mental health professionals [and have] ined their workers in techniques of individual, group, and mily therapy." These informal efforts have been comemented and enlarged by formal recruitment of mental alth professionals. Nationally, 25%–35% of the counselors runaway centers have M.S.W.s, and almost all of the rest ve undergraduate majors in psychology, social work, unseling, education, or child development. The credenils and training of this direct service staff are comemented by the consultants available to runaway centers: most every program has a psychiatrist or Ph.D. psycholost involved in providing services or consultation. Finally, der the terms of the Youth Development Bureau's technil assistance contract with the Educational Systems Corpotion each of the 150 federally funded runaway programs is so involved in 9–10 days a year of training workshops.

In settings where much of the staff has received advanced ofessional training, where all staff members are keenly vare of the techniques used by mental health professionals, e "diagnosis and treatment regimens" are anything but elatively poor." Although the diagnostic labels that are stomarily used in psychiatric practice are rarely applied to naways, the level of sensitivity to the psychosocial situaon of each young person seems as high in most runaway ograms as it is in most psychiatric centers for troubled olescents.

Finally, though there is indeed an exploitation of runays by older people who live on the street or in the neighorhoods of some runaway centers, I have seen very little idence that "sociopathic teenagers . . . take full advantage the other adolescents" in the runaway center itself. The sy communication between staff and clients in a runaway nter, the constant presence of counselors, and the daily ouse meetings militate against the secrecy and authorarianism that foster bullying and exploitation. My impreson is that fighting and exploitation occur no more and perps less often than they do in mental hospitals, schools, or the street.

I would suggest that Dr. King visit Runaway House, Inc., Memphis, Tenn., for a firsthand look at the kind of training that the counselors receive (*all* of the primary counselors ve master's degrees in one or another of the human servces fields) and that other psychiatrists who are particularly concerned with adolescents and their families contact the Youth Development Bureau (the Humphrey Building, Washington, D.C. 20201) for the names of runaway centers near them. The runaway center is an extremely valuable mental health resource.

JAMES S. GORDON, M.D.
Rockville, Md.

Difficulties with Retrospective Studies

SIR: In "Discriminating Features of Borderline Patients" (July 1978 issue), John G. Gunderson, M.D., and Jonathan E. Kolb, M.D., presented an excellent study but misrepresented the results. Their statistical methods have been criticized in the past (1, 2). These methods make theirs a retrospective study because key statements (DIBs statements) and sections of dysfunction are identified and weighed appropriately (by means of standardized coefficients) *after* the patients are assigned to either the borderline or control groups. This stepwise discriminant function analysis gives the "best fit" for the patients who are already placed in certain diagnostic categories, but the fit would not necessarily be as good with prospectively chosen patients. Certainly, the diagnostic accuracy would be much less than the 81%–100% found in this study. This is a retrospective method, and the next logical research step would be a formula that weighs each DIBs statement and section score in accordance with the standardized coefficients the authors found in this study and application of this formula prospectively to a mixed group of patients.

Because this is a retrospective study statistically, the conclusions are overdrawn. They have not "shown that borderline patients can be discriminated with high accuracy from matched comparison groups." Instead, this study has shown that once a patient has been given a presumptive diagnosis of borderline disorder, then certain statements are more likely to be true (or false) about this patient than about patients with other diagnoses. This study neither strengthens nor weakens the argument that there exists either a "recognizable personality disorder," or a "definite syndrome"—nor does it provide a "replicable means for identifying borderline patients." That must still be done by using these data in a prospective fashion.

FREDERICK W. ENGSTROM, M.D.
Minneapolis, Minn.

Drs. Gunderson and Kolb Reply

SIR: Dr. Engstrom is thoughtfully conservative in his interpretation of our study. Although the diagnostic accuracy of 81%–100% we achieved is suspiciously high, there is nothing inherent in the methodology to suggest that "the diagnostic accuracy would be much less." In fact, we applied the discriminant function prospectively to a different sample of 29 independently diagnosed borderline patients and found

that it accurately identified 22 (76%) of them. Despite these encouraging results we can agree with Dr. Engstrom that our study is exploratory, and a more definitive replication using randomly selected patients is warranted. We have provided a methodology and isolated clinical variables to make this feasible. In the meantime, it seems reasonable for anyone wishing to define borderline patients to use the set of discriminating criteria we have reported.

A Cannabis Caveat Reinforced

SIR: The article "Marijuana Use in Schizophrenia: A Clear Hazard" (October 1978 issue) by Darold A. Treffert M.D., is a timely caveat. Those of us whose practices include large numbers of adolescents anxiously search the literature for documentation of our repeatedly confirmed observation that marijuana is a psychiatrically deleterious drug, especially for vulnerable or unstable youths.

I am certain that the literature would contain many more such observations if clinicians actively sought to make the temporal connection between marijuana use and acute psychotic episodes. A good case in point is another article in the same issue of the *Journal*, titled "Hyperthermia Associated with Chlorpromazine and Full-Sheet Restraint." Drs. Greenland and Southwick called our attention to an important association but failed to underscore another important association, which they state explicitly but without comment. I refer to the fact that their 18-year-old patient was well until 2 weeks before admission when his acute symptoms of psychosis began. "He also expressed considerable guilt about *recent frequent marijuana* use. He did not use any other licit or illicit drugs, including alcohol" (emphasis added).

I am indebted to Dr. Treffert for recording his observation and to the *Journal* for publishing it. I would hope that this type of observation will influence those who still entertain doubts about the untoward and adverse effects of cannabis.

DORIS H. MILMAN, M.D.
Brooklyn, N.Y.

Diagnostic Issues in Bromism

SIR: "Bromism: Alive in Well" (July 1978 issue) by Ira Brenner, M.D., was an interesting case report, but I would raise several questions about the author's assumptions.

Contrary to Dr. Brenner's claim, there has been a reported case of bromism caused by chronic drinking of well water (1). Furthermore, the patient in Dr. Brenner's article could have been experiencing alcohol withdrawal rather than bromism; her alcohol consumption increased during the week before admission, and on entering the hospital she displayed restlessness, poor memory, and a tremor, all of which resolved quickly during hospitalization. We are not told the patient's blood alcohol or admission or her vital signs during the period of symptom improvement. Moreover, only one high serum bromide level (38.3 mg/100 ml) was reported, and the level apparently returned to normal within one week. If only one serum bromide level was abnormal, the possibility of a laboratory error cannot be ruled out, especially in light of this patient's rapid improvement. Although Dr. Brenner makes a good case in incriminating the well water as a cau of bromism, I think substantial evidence seems to be lackin

CHARLES B. SCHAFFER, M.D
Chicago, Ill.

Dr. Brenner Replies

SIR: I appreciate Dr. Schaffer's interest in my article a would like to respond to his hypothesis that alcohol wi drawal and/or laboratory error could account for the tient's clinical picture. On admission, she was not toxicated and did not smell of alcohol, so alcohol levels w not obtained. Her consumption of alcohol was about beers a day, but she did not experience significant alco withdrawal. She did not have autonomic instability, el trolyte imbalance, or subjective feelings of shakiness, a she received only 10 mg of diazepam during her entire hos talization. Her agitated depression did resolve quickly, w tremor and hopelessness diminishing by the end of the f week without specific treatment. However, the effect of hospital milieu itself on her improvement is a factor tha more difficult to assess. It should also be noted that when returned from a weekend at home, her bromide level creased to 15.9 mg/100 ml, after it had decreased to and l eled off at 5 mg/100 ml. This was another instance of consumption of well water correlating with an increase serum bromide level, and we felt that the laboratory resu were reliable. The well water was also assayed and found have a 2.1 mg/100 ml concentration of bromide.

Nevertheless, the substantial evidence that Dr. Schaffe seeking implies a need for many more clinical data, and can begin with the reference that he cited.

Sex Chromosome Anomalies and Manic-Depressive Illness

SIR: I should like to comment on the letter from Jacq Lesage, M.D., and Guy Chouinard, M.D., about "Mar Depressive Illness Associated with Klinefelter's Syndro and Essential Tremors" (June 1978 issue). Although the thors are right to point out that this observation is in line w the X-linked dominant hypothesis of inheritance in ma depressive illness (1, 2) and may possibly explain some parent cases of father-to-son transmission of the disease their suggestion that the case was the first to be repor with both illnesses is incorrect. In another section of issue, Stanley N. Caroff, M.D., reported on a patient w both syndromes and noted that eight such cases have b described previously.

Nevertheless, this type of observation has theoretical plications for the inheritance of manic-depressive illn since according to the sex-linked dominant hypothesis, tients with the XXY constitution may be expected to hav greater incidence of manic-depression than XY males cause they behave genetically like females. Conversely,

its with the XO genotype (Turner's syndrome) may be s prone to affective illness than normal XX females. To knowledge, there have been no reports to date of an as-iation between Turner's syndrome and manic-depressive ess. The question of potential associations between sex omosome anomalies and manic-depressive illness de-ves further attention and can only be answered through ll-designed epidemiologic studies.

Brussels, Belgium

s. Lesage and Chouinard Reply

SIR: As Dr. Mendlewicz points out, our case report is not first one describing the association of Klinefelter's syn-ome with bipolar affective disorder. However, it is, to our owledge, the first report of these two illnesses associated h hereditary essential tremor. The point we wanted to phasize was that similar cases could explain the father-to-n transmission of bipolar affective disorder and should be minated by chromosomal analysis before suggesting that it incompatible with the X-linked dominant inheritance of olar affective disorder. It should also be noted that even a gative result on chromosomal analysis does not entirely minate Klinefelter's syndrome, since some patients may ve pure gonadal dysgenesis, i.e., the phenotype of Kline-ter's syndrome with a normal chromosomal analysis.

Another phenomenon that may also explain the observed her-to-son transmission of bipolar affective disorder is saicism, which (although rare) could result in father-to-n transmission of a bipolar affective X-linked dominant ne despite normal chromosomal analysis. Finally, we uld suggest that in cases of father-to-son transmission of olar illness, a complete genital physical examination ould be performed in order to eliminate Klinefelter's syn-ome or sexual mosaicism associated with affective illness.

Montreal, Que., Canada

Defense of the Hypothetical-Deductive Method

SIR: There has been considerable criticism (1, 2) of the thodology described by Silvano Arieti, M.D., in "Psy-otherapy of Severe Depression" (August 1977 issue). ere seems to be a tendency to reject any methodology that es beyond the purely descriptive and phenomenologic radigm. Although this approach is a sine qua non for a ience of human behavior, there is certainly a place for the pothetical deductive method, which uses a theoretical mework as a heuristic approach for intervening in a therapeutic manner with patients who are seriously disturbed.

This heuristic approach can also serve as an interim means of representing the data observed until there are data sufficient to further modify the theoretical framework. Freud recognized the ultimate psychobiologic basis of severe mental illness, which he designated the narcissistic neuroses. Dr. Arieti has done no less in his interpretation of schizophrenia (3), where he presents a tentative model of schizophrenia as a psychophysiologic disturbance of the central nervous system. Needless to say, his model is based on considerable observational data, which include the probable evolution of cognition from paleologic to secondary process thinking. I might add that much of Dr. Arieti's work will probably be validated empirically in the future as we learn more about the functions of the right and left cerebral hemispheres. Stevens' work (4) on a possible gating mechanism in the mesolimbic system will probably also play a role in elucidating the underlying pathophysiology of true process schizophrenia.

It is my opinion that with our new knowledge of the central nervous system and its function, coupled with the clear understanding that all knowledge is influenced and modified by the participant observer, both the nomothetic and idiographic methods of investigation as described by Dr. Arieti must be employed if any workable conceptual framework of human behavior is to be formulated. The fact that the human central nervous system processes data at a neocortical level as well as at lower levels provides substantial evidence to indicate that Dr. Arieti's psychodynamic form of intervention can have definitive effects on how the individual processes his perception of reality. Psychodynamic intervention can be more than anecdotal, and a modified science of human behavior based on observation and psychological intervention can evolve. I refer those who find this idea difficult to accept to Dr. Arieti's *Interpretation of Schizophrenia* (3) and to Hans Reichenbach's *The Rise of Scientific Philosophy* (5) wherein he points out that the hypothetical deductive method is a special form of induction.

Wauwatosa, Wis.

Jealousy and Nontraditional Marital Units

SIR: In his article "Pathological Tolerance" (June 1978 issue) Emil R. Pinta, M.D., followed traditional psychiatric thinking by reporting three triads within a framework of marital and personal pathology. Although it is true that there were problems in all 3 cases after the introduction of the third person into the relationship, this does not necessarily mean that the relationships or the psychodynamics are evidence of pathology. Dr. Pinta reports no data on the quality of the dyadic relationship before the addition of the third

partner, so it is impossible to gauge the effect of the third partner on these relationships. Certainly, societal disapproval and lack of responses in individual behavioral repertoires (due to a lack of socialization for triadic marital experiences) may be a factor in the development of the problems noted by Dr. Pinta.

Dr. Pinta states that "the emotional involvement among members of the triadic unit, the stability of the unit, and the absence of three-person sex are characteristic features of this symptom complex and distinguish it from . . . other nonmonogamous sexual lifestyles." From this statement, it seems that he is unfamiliar with the work of Constantine and Constantine (1), who found that group marriages were often characterized by intense emotional involvement among the members of the group and that the group marital situation was used by members as a vehicle for nonneurotic need satisfaction and personal growth. Other workers who have investigated alternative sexual lifestyles have pointed out the potential for intimacy and maturation within such units and have noted the relative absence of neurotic pathology (2, 3).

Psychiatrists need to devise new techniques for working with nontraditional marital units. One such methodology would be marital therapy with all three members of the triad. Constantine (4) and Blood and Blood (5) have worked extensively with nonpathological jealousy within such units and have also devised new therapeutic techniques for working with jealousy. Psychiatrists should be careful to avoid automatically labeling nontraditional lifestyles and their participants as "deviant" or "pathological" and should seek to identify, from the participants' point of view, the benefits of such lifestyles. Therapy should be aimed at the resolution of problems within the context of the participants' goals for treatment, not according to the bias of the psychiatrist.

KENNETH SOLOMON, M.D.
MONA SOLOMON, M.S.
Richmond, Va.

Dr. Pinta Replies

SIR: The comments made by the Solomons raise important questions regarding the nature of jealousy and the opposite attitude, tolerance. Traditionally, jealousy has been regarded as a sign of healthy commitment to a valued partner. Freud expressed this viewpoint when he wrote that jealousy is a normal feeling, much as grief is. If anyone appears to lack jealousy the inference is that it has undergone repression and therefore will play an even larger role in the unconscious (1). There is, however, another attitude toward jealousy that emerges from experience with nonmonogamous lifestyles (such as open marriages, swinging, group marriages, etc.). This viewpoint regards jealousy as an unhealthy sign of possessiveness and dependency that indicates an inability to care and allow for the development of one's partner. Studies by Constantine and Constantine and others quoted by the Solomons appear to substantiate this opinion. Furthermore, the flexible nature of jealousy is borne out by sociological comparisons and by experimental communities such as the one at Twin Oaks (2).

I did not mean to state in my article that all tolerant extramarital relationships are pathological. Each situation must be regarded separately. In the cases I presented the tolerant attitude of the spouse seems to be a pivotal dysfunctional element in the marital relationship. I also feel that the extramarital nature and stability of the described relationships promoted the acting out of unconscious psychological mechanisms more than many other lifestyles would. I agree with the Solomons that those of us in the mental health field must try to avoid labeling as pathological lifestyles that differ from our own or from our view of normalcy. As in the case of jealousy, tolerance should be regarded as dysfunctional or pathologic only when it appears to interfere with personal growth and interpersonal relationships in a chosen lifestyle.

Corrections

In the November 1978 Official Actions section (p. 14[illegible]) the name of Om Prakash, M.D., was misspelled.

There was an error in table 2 of "Prediction of Individual Dosage of Nortriptyline" by Thomas B. Cooper, M.A., and George M. Simpson, M.B., Ch.B., in the March 1978 issue. Blood levels are given in ng/ml.

The staff regrets these errors.

OOK REVIEWS

ress Disorders Among Vietnam Veterans: Theory, Research id Treatment, *edited by Charles R. Figley, Ph.D. New ork, N.Y., Brunner/Mazel, 1978, 311 pp., $15.00.*

The United States military involvement n Viet Nam be- n in earnest during the bold and exuberant presidency of hn Kennedy and ended with the disorderly evacuation of e American Embassy in Saigon in April 1975. The slide om the exhilaration of Camelot to the cynicism of Water- te was unexpected and unsettling. Ever now it remains fficult to write with moderation about this epoch and its ajor casualties—the Viet Nam veterans.

The editor introduces this book by setting out six goals: 1) define the construct of Viet Nam-related combat stress sorders, 2) to alert mental health professionals to the theotical and clinical importance of these disorders, 3) to perade the reader that the residue of combat stress transcends ne and situation, 4) to remind the reader that little is known out long-term results of catastrophic combat experience, to provide treatment guidelines, and 6) to expand the owledge base of combat-related stress disorders. These e ambitious tasks to accomplish in one volume, they are ade even more elusive by the editor's attempt to be evenhded. Twenty-four authors contribute to this book. The ader will recognize the names and views of well-known tiwar activists as well as those of some career military ental health professionals.

Two representative points of view seem in conflict. The st hypothesis is that the military experience in Viet Nam as unique and traumatic because of the inherent nature and vagery of the conflict, the elusive character of the enemy, e impact of individually tailored one-year duty rotations, d the ambivalent homecoming accorded combatants. The ediction made in this view is that initial opinions about the ccessful adjustment of veterans will not stand the test of ne and that many veterans will seek help months and years er for delayed catastrophic stress disorders (post-Viet am syndromes). The second hypothesis is that attempts to ribute the problems of veterans to their unique experience Viet Nam does not withstand scrutiny and does not lead to ique symptomatology. It is suggested in this view that ose who have had the most difficulty during military duty d as veterans are those who already had the greatest numr and kinds of preexisting handicaps in personal skills.

The text is divided into three major sections involving thetical formulations, some representative research reports, d suggestions for treatment of this special veteran popuion. The first and third divisions include papers based on erature reviews and clinical experiences with an emphasis psychosocial perspectives. The section on research reorts presents the results of descriptive follow-up studies th appropriate statistical analyses. Sixty-one pages in this tion are used to reproduce the various research inument questionnaires; this will not likely prove useful to ost readers.

Sober reflection suggests that, for many, the war in Viet am is still not over and the need for mental health services targeted for Viet Nam veterans continues and may increase. This book provides a service to those who work with veterans by examining pertinent treatment issues and offering relevant suggestions for therapeutic interventions that may be useful in making the mental health professional better informed and more empathic.

WILLIAM D. WEITZEL, M.D.
Lexington, Ky.

A Child's Journey: Forces That Shape the Lives of Our Young, *by Julius Segal, Ph.D., and Herbert Yahraes. New York, N.Y., McGraw-Hill Book Co., 1978, 336 pp., $10.95.*

Dr. Segal, Director of Public and Scientific Information Programs of the National Institute of Mental Health, explains in his introduction his aim in coauthoring *A Child's Journey:*

> My aim was to produce neither a traditional textbook nor a How To Manual of Child Rearing but a resource grounded on research findings for all of us who care about children and who want, therefore, to know more about why they develop as they do and what they can and cannot do to shape the outcome of their journey.

Dr. Segal's editors add that the book was written particularly for parents but that it is also addressed to all adults "who deal in any way with children—teachers, doctors, psychiatrists, psychologists, social workers, lawyers and judges." It is perhaps unfair to ask a child psychiatrist to review this book for an audience that will consist primarily of psychiatrists because this is not the expressed target audience of this volume.

It will come as no surprise to the reader who scans between the lines that this book presents nothing new, exciting, startling, or stimulating to the adequately trained child psychiatrist who keeps up with recent developments in either the professional press or the Sunday magazines. However, it presents a well-thought-out, nonjudgmental integration of many theories of child development and associated research findings. The authors look at genetic and environmental factors in child development. They describe factors that other lay authors have often neglected—fathers, peers, schoolteachers, poverty, and racism. The research findings are presented in an objective way and are not confused with graphs, statistics, and other technical decorations, which would serve the lay reader. However, the authors' biases are apparent in the research findings they choose to highlight: one chapter is devoted to genetics and at least seven chapters to environmental factors. Even the casual reader has some hint as to the authors' predisposition about important factors in child development.

The final chapter, titled "Protecting Your Child's Mental Health," is probably the most important one for concerned, politically active psychiatrists. The authors summarize the

points they feel are the most important in the preceding 12 chapters, such as the importance of planning for, wanting, and anticipating children; recognizing and accepting children's individuality; the critical nature of the early mother-infant attachment; and the importance of a stimulating environment. The relevance of the relationships between fathers and their children, the importance of peers, the effect of malnutrition on child development, and the poisons of racism are also highlighted. This chapter is more than a summary. The authors exhort their readers to become involved in lobbying "for children" and "for the sake of children." They stress the need for an informed public advocate to enunciate their concerns about tax reform, reorganization of health care, racism, sexism, and energy as these political and critical issues impact on child health and development. They also exhort their readers to care for children and to commit themselves to child welfare. No respectable child psychiatrist can argue with the final line of this passionate sermon.

ELISSA P. BENEDEK, M.D.
Ann Arbor, Mich.

Methods of Group Psychotherapy and Encounter: A Tradition of Innovation, *by Jerrold Lee Shapiro. Itasca, Ill., F.E. Peacock, 1978, 354 pp., $12.50.*

Perhaps the best measure of this contribution to the literature is signaled by the 48 pages of reference and the 5 pages of index. The work encompasses the history of group therapies over a broad expanse of time. It covers a broad range of styles of leadership and applications. Most helpful is the liberal citation of authors in connection with each aspect of group psychotherapy under consideration. This makes it an ideal companion piece to Yalom's text (1). At times the careful documentation obstructs the easy flow of the book, but at the same time it generates an extremely valuable source book for anyone embarking on a program of work and learning in this field.

Inclusion of excerpts from group therapy sessions is a very helpful way to convey the essence of the various styles the author uses in making the multiform communication of the group more intelligible. By doing so, however, he had to be selective and could not cover all variations of group treatment procedures. This does not materially detract from the book, but it does contrast with its global reach.

For an overview and an introduction to the literature this is a substantial book. It is also a useful tool for the teacher of group psychotherapy who plans to present the entire field rather than one specific approach.

JAY W. FIDLER, M.D.
Piscataway, N.J.

Psychiatric Examination in Clinical Practice, *by J.P. Leff, B.Sc., M.D., and A.D. Isaacs. Oxford, England, Blackwell Scientific Publications (Philadelphia, Pa., J.B. Lippincott Co., distributor), 1978, 143 pp., $11.75 (paper).*

Those of us in psychiatry who have learned to think predominantly in terms of intrapsychic conflict as having great etiological and diagnostic significance pay almost exclusiv attention to the form and/or content of patients' mental pr ductions, which are elicited by a verbal interchange. The a thors of this book are to be commended for bringing to th reader's attention the fact that observation, study, ar classification of a patient's behavior can be most helpful understanding psychopathology. Furthermore, others ca view the same behavior and arrive at a basis for agreeme and standardization.

This wonderfully brief book contains a wealth of inform tion and clinical wisdom. It begins by drawing attention t the need for careful, systematic observations, beginning wi the initial contact with the patient. The reader soon becom aware of the authors' capacity to make terms and concep explicit and to use clinical vignettes for further elucidatio The few drawings amplify some of their major points. Or gets a very vivid impression of what is being described. Le and Isaacs have attained their goal of setting down phenom na in such a way that clinicians who follow their guidelin can attain diagnostic concurrence.

Although the two chapters on taking a history describe method and style that I have generally set aside, they cov all the essential points in an orderly way. The reason th this technique has been found inadequate is that it is possib for the clinician to be misled. Repression and denial mig cause the patient to leave out essential material when th structured question-and-answer type of interview is used. is not enough for the interviewer to know all the right que tions to ask. Patients reveal more of themselves when the feel that the interviewer is "tuned in" to them. Perhaps th is more important when dealing with neurotic symptoms.

It is hard to understand why neurotic symptoms a grouped in the same chapter with affective ones. This rais the question of what audience the authors had in mind f their book. The inclusion of a chapter on childre makes appear geared to a general readership. However, the are covered most intensively (present mental state, delusion hallucinations, organic conditions, and affective symptom pertain to a hospitalized or equivalently ill group.

In summary, this book has some excellent feature: lucid ty, specificity, graphic description, brevity, and emphasis c observation. Its weak point is that it does not amply cov neurotic symptoms and personality disorders. Instead, it i cludes a section on the examination of children, which mig be beyond the skill and experience of a general psychiatris Nevertheless, it is well worth reading for practitioners as refresher and for students as a primer. They will find subt points of clinical wisdom expressed in a readable and mem rable fashion.

ROBERT W. ATKINS, M.D.
Rochester, N.Y.

Freud in Germany: Revolution and Reaction in Science, 189 1907. Psychological Issues Monograph 41, *by Hannah . Decker. New York, N.Y., International Universities Pres 1977, 348 pp., $15.00.*

A first impression that the period from 1893 to 1907 is t short for an exploration of the reception of psychoanalysis Germany is dispelled by reading Hannah Decker's boo Freud himself considered the first stage of reception to ha ended around 1907. That year Karl Abraham returned fro clinical work in Zurich and a visit to Vienna and establish a psychoanalytic psychiatric practice in Berlin.

Decker begins with a description of German culture and ociety. Then she divides her book into three parts: one on erman medicine and psychoanalysis, a second on the new" psychologists and psychoanalysis, and a third on the ducated German public and psychoanalysis. In each part he considers particular elements, such as the unconscious, reams, sexuality, and psychopathology. These sections ake it possible to focus on specific elements that varied in ow they were received by the three groups, but it also akes for repetitiveness.

German psychiatry was primarily interested in the psyhoses. Psychiatry and neurology were allied, and the laboatories for brain anatomy and experimental psychoathology in university settings were prestigious. Kraepen's clinical classification of diseases appeared in 1896 in his extbook, which exercised a decisive influence. The "new" sychologists stressed experimental methods and did not onsider psychopathology part of their field. Germany at the ime was not a fertile field for psychoanalysis.

Freud himself did not facilitate as much as he could have he favorable reception of his pioneering work. He did not ttend general medical meetings, did not publish in widely ead journals, and was slow to reveal the nature of his psyhoanalytic technique and its separation from hypnotism. le was identified with hysteria, considered to be an un-Germanic condition, and with childhood sexuality, a sensitive ubject in Wilhelmine Germany.

Decker attacks Ernest Jones as the official codifier of reud's view that his work was ignored and that what attenion it got was unrelentingly hostile. She refers to two myths: One is that for about ten years after *Studies on Hysteria* ppeared, Freud was uniformly ignored and rejected. The econd is that all real opposition to psychoanalysis centered n sex" (p. 172). I found her presentation of a varied and omplex reaction to Freud's work convincing.

Eugen Bleuler and C.G. Jung, although based in Zurich, ere very influential in Germany because they published in he German literature. Their propsychoanalytic positions ere invaluable. Many Americans at that time learned about sychoanalysis through Bleuler and Jung, who, in contrast o Freud, were hospital-based. Since psychiatrists in both ermany and America were primarily working in hospitals ith psychotic patients, Zurich was crucial to the spread of sychoanalysis. Karl Abraham worked at Bleuler's hospital efore returning to Berlin to practice psychoanalytic psychitry.

This book is illustrated with pictures of Abraham, Aschafenberg, Bleuler, Hellpach, Kraepelin, Stern, Wundt, Zieen, and several others whose positions and statements bout psychoanalysis are selectively quoted by the author. n addition to the references the author lists 33 interviews he conducted between 1963 and 1968, primarily with German psychoanalysts who came to the United States. Decker as written a valuable work that provides an understanding f what transpired in Germany and also illuminates the comarative reception of psychoanalysis elsewhere.

The Experience of Depression, *by Dorothy Rowe. New York, N.Y., John Wiley & Sons, 1978, 273 pp., $19.50.*

One of the most critical challenges facing both the clinician and the researcher is the need to reconsider the nature of depression. Only by the discovery of new hypotheses can the wide variety of information relevant to this issue become more deeply understood and more properly integrated. In our understanding of the phenomenon of depression, the field of psychiatry has moved steadily from a more descriptive position delving from a psychoanalytic point of view into some of the intrapsychic forces that generate depression to broader concepts that consider the significance of biological influences as well.

In this book the author explores another dimension, the environment of the depressed patient or, more particularly, the nature of the more intimate human interactions between the patient and key people in his environment. The author's approach is more than simply transactional. She explores the pertinent premises that affect the individual's perception of himself and others and that are expressed and colored by the very language used to form contact.

Dr. Rowe's work is essentially a report of a clinical investigation using special interviewing strategies carried out over a period of several years with a limited number of patients subject to depression. In the context of psychotherapy she explores at length the relationship between depression, the way the patient experiences himself and reality, and the approaches used to help patients recover from depression by modifying some of their critical assumptions. These assumptions have set the stage either for depression or for the recurrence or tenacity of a disabling emotional state.

This book will certainly be of interest to anyone who is seriously involved in depression research. Its value for the practicing clinician and the teacher, however, is decidedly limited. Much of the presentation consists of detailed case histories and experiences in the course of therapy that are rewarding only to substantiate Dr. Rowe's thesis. In a more fundamental way, although her observations stimulate the reader's thinking, they do not—for a variety of reasons (including the limitations in the style and manner of presentation and in the way her conclusions are drawn and discussed)—offer a significant new insight into the problem under study.

Cultural Conceptions and Mental Illness: A Comparison of Germany and America, *by John Marshall Townsend. Chicago, Ill., University of Chicago Press, 1978, 148 pp., $11.00.*

Townsend, an anthropologist, contrasts what he calls the social role approach to mental disease with the clinical universalist approach. The social role approach implies that there should be a broad cross-cultural variety in symptoms because symptoms are social roles and should be specific to particular cultures. Traditional clinicians claim that the signs and symptoms of mental disorders (particularly schizophrenia) are universal and that societal reactions to these symptoms are similar throughout the world.

A variety of tests given to approximately 100 mental patients, 100 mental hospital staff, and 500 high school students from both the United States and Germany revealed massive differences between German and American concepts of mental disorder. Germans tended to believe that mental disorder is biologically caused and is not affected by the environment. Americans tended to believe that mental disorders are, at least in part, a question of personal willpower and are strong-

ly influenced by factors in the social situation of the individual. American patients were more likely to consider mental disorder "curable" than German patients. American patients also tended to cite disturbed or bizarre physical characteristics as "diagnostic" criteria of mental illness, whereas German patients tended to cite disturbances of mental functions, cognition, and judgment. These differences affected the ways in which patients coped with the hospital setting. For instance, 79% of the German patients felt that only a doctor could decide when a patient should be released, but only 49% of the American patients gave this opinion. American patients emphasized compliance with hospital regulations to obtain release (47%), but only a few German patients gave this response (5%).

Townsend reviews the literature on social labeling and clinical universalism and comes to the conclusion that neither side is right. He argues that some of the confusion is caused by the different patient populations considered by the opposing theorists. He suggests that less extreme or middle-range cases may be more susceptible to social labeling and so are cited by theorists who favor this viewpoint, while more extreme cases provide better examples for universalists. He proposes a model that he feels reconciles the two camps. However, this leads him to the psychiatrically dubious position that, at least at one level, psychiatrically disturbed patients in the beginning consciously "put on" their disturbed behavior.

I was disappointed with this book. The author approaches the problem of mental illness from the viewpoint of the social role theorist, an approach that is somewhat confusing to psychiatrists because it uses some psychiatric terms (e.g., "conversion") in a different sense. Acceptance of the sick role by mental patients does not necessarily signify conversion to the disease concept but may be a progressive step, as in conversion hysteria and hypochondriasis. Development of additional symptoms during hospitalization may be due not to the prescribed and imposed sick role but to ego regression.

Because of its focus on social role, this study does not explore other aspects of transcultural differences in psychopathology. I would suggest that length of hospitalization of mental patients depends more on their clinical condition than on other considerations. Townsend conveys the impression that the opposing camps of clinical universalists and social theorists are large, but in fact most contemporary psychiatrists occupy the middle ground. Although he tries to reconcile the social role approach with the biological approach in one chapter, a much more comprehensive view of the problems involved seems to be needed. In particular, the complete disregard of intrapsychic problems in this book is regrettable.

Montreal, Que., Canada

Language and Cognition in Schizophrenia, *edited by Steven Schwartz. Hillsdale, N.J., Lawrence Erlbaum Associates (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1978, 276 pp., $18.00.*

This volume presents the research efforts of major investigative teams who have examined the language of schizophrenic patients as a sample of their abnormal behavior. The hypotheses tested range from the idea that language and cognitive style are aberrant social phenomena in the interpersonal process of the schizophrenic patient to the idea that they are related to asymmetrical brain function. The variou measures described in the studies reported are exact, e haustive, and sometimes excessive. A critique leveled b one of the authors is that each chapter seems to justify th validity of a hypothesis by "good" research design. Sever chapters are difficult to read because they contain exhau tively detailed data but only a limited discussion of co clusions from these data.

In a chapter on the lack of progress in the understanding c cognition in schizophrenia, Blaney points out that a failure study proper subsamples of schizophrenic patients is a maj error. I have also often wondered whether poor communic tion efforts by schizophrenic patients compared with contr subjects might be explained by a major difference in motiv tion.

The chapter by Oltmanns and Neale provides a ver thoughtful critique of some of the best research efforts in th scope of this volume. These authors direct their attention t distractibility in schizophrenia as a major psychological de cit that seems to be correlated with genetic predispositio Building on the reader's preparation by the preceding cha ters for the investigation of a biological basis for the hypot esized psychological deficits in cognition and perception schizophrenic patients, Shimkunas develops a very readab analysis of the data regarding the hypothesis that cerebr asymmetry accounts for some major theories—Chapma and McGhie's "filtering deficit" hypothesis, Salzinger "immediacy" hypothesis, and Bleuler's "associational deficit.

The editor of the book does not attempt the impossible his chapter; he does not summarize and integrate the maj conclusions of the rest of the chapters. Rather, he presents review of important literature and published critiques of th substantive theories of cognition and language as behavi variables in the schizophrenic syndrome. On the basis of th review he produces an inclusive schema for a more "defin tive" study of schizophrenic language.

This volume provides a description of the "state of th art" as well as an outline for more definitive work needed t establish a fuller biological and psychological understandin of cognitive, perceptual, and communicative behavior in th schizophrenias.

JAMES R. STABENAU, M.D.
Farmington, Conn.

Power and Authority in Adolescence: The Origins and Resolutions of Intergenerational Conflict. Publication 101, *by th Group for the Advancement of Psychiatry Committee c Adolescence. New York, N.Y., GAP, 1978, 213 pp., $6.5 (paper).*

This unusually well-written and balanced monograph is con cerned with power struggles and accommodations betwee the generations. It addresses broader issues as well. The au thors acknowledge that the adolescent/adult interface ha changed dramatically since work was first started on th monograph. At that time adolescents and adults in Weste culture seemed much more sharply at odds with one anothe —divided over such issues as Viet Nam and drugs. Howeve the present work is not irrelevant. Power and authority issue between the generations will always be germane because th progressive assumption of authority is necessary to a healt adolescence and the relinquishing of some authority is re quired of adults.

The authors consider power and authority issues from in-apsychic, intrafamily, intracultural, and intercultural per-ectives, maintaining a primarily psychoanalytic orienta-on. Considerable weight is given to the shift away from a ell-defined patriarchal society. It would have been of inter-t if the authors had searched for other, smaller changes in ılture that might account for the increased polarization be-/een the generations 5–10 years ago and for its subsequent minution. The committee did not assume that the shift om a strictly patriarchal model applies equally across all cioeconomic groups. In fact, I found the authors' sensitivi-to "minority" perspectives, whether in terms of race, ec-ıomics, or sex, particularly praiseworthy.

Approximately one-third of the book is concerned with a ychoanalytic review of child development. This might ap-ar to be an unnecessary expenditure of space, since so ny excellent descriptions of childhood development are ailable elsewhere. Careful reading, however, shows that e authors weave the tracing of power and authority issues roughout their consideration of child development. The imary determinants of such issues take place in the forma-e years of child development within the context of the nu-ar family. The vicissitudes of these struggles between the nerations in childhood can be traced specifically to each ase of psychosexual development. In addition to under-nding this from the viewpoint of the individual child, the thors illustrate how parents who have had difficulties in solving certain of their own conflicts at various levels of velopment are prone to interfere with their children's res-ıtion of similar or dissimilar conflicts.

Having retraced childhood development from the point of ew of the authority/power issue, the authors examine cer-n dynamics and phenomena of the authority gap (e.g., nflict within the family, student-school conflict, sexuality, d drug use). They also include an interesting discussion of w adolescent musical tastes portray many adolescent au-ority and power issues.

The role of psychiatrists in helping families deal with ado-scent/adult authority issues is briefly presented. "Negotia-n" as a therapeutic technique is offered as a model for ervention in family therapy. Although the authors are reful to indicate that there are many other ways to ap-oach family therapy, the fact that this is the only model esented in the book seems somewhat a departure from its herwise carefully balanced and even-handed presentation. owever, it may be that negotiation is a particularly suitable hnique for families trying to deal with authority and pow-issues. More clinical examples scattered throughout uld have been helpful but would have compromised the evity of the monograph. All in all, the book accomplishes aims in a sensitive, optimistic, and constructive manner.

HOWARD S. SUDAK, M.D.
Cleveland, Ohio

e Hite Report: A Nationwide Study on Female Sexuality, *by ere Hite. New York, N.Y., Macmillan Publishing Co., 76, 438 pp., $12.50.*

This report is a compilation of 3,000 responses to 4 dif-ent questionnaires designed by the author. The partici-nts were a self-selected group of women recruited through ilings to various national women's organizations, through urch newsletters, and through notices placed in several gazines. Although the validity of this research design is questionable, the book does replicate some findings of earlier, more carefully controlled research projects. The report finds that clitoral stimulation resulted in the most intense physiological orgasms for these women, that only 30% of the participants climaxed regularly from vaginal stimulation alone, and that there was a high correlation between a history of no masturbation and inability to achieve orgasm.

The book is organized to emphasize the content of the respondents' answers rather than to present a statistical breakdown of responses. This descriptive material of sexual feelings and practices is of some interest and value to the psychiatrist. Unfortunately, much of it is presented to create complaints about men. The author's thesis is that current heterosexual physical interaction reflects the inferior status of women in our culture in general. This thesis creates a bias in her presentation of material. For example, in dealing with responses regarding stimulation of women by men, the author emphasizes men's selfishness, ineptness, or, at best, ignorance. This bias becomes particularly evident in the chapter on lesbianism, in which, by contrast, lovers are portrayed as invariably sensitive, considerate, and skilled.

The author pays little attention to the woman's role in letting her partner know what she needs; she represents the man as unwilling to listen. The author's bias also causes her to characterize intercourse as an overvalued form of sexual interaction, developed in the interest of procreation and male satisfaction. The majority of her female respondents, however, claimed that intercourse was important and gratifying, whether or not it was their primary means of achieving orgasm.

The more positive aspects of the book—the chapters on the importance of touching and on varieties of sex play that do not necessarily end with intercourse—are echoed by most sex therapists today. The book also raises several important social issues, including the effects of the sexual revolution on woman's status in society, the sexual options for today's older woman, the effect of a woman's economic position on her sexuality, and sexual pleasure as a panacea for societal ills. From the psychiatrist's point of view, little emphasis is placed on intrapsychic dynamics or interpersonal needs as factors in sexual behavior.

VIRGINIA A. SADOCK, M.D.
New York, N.Y.

Early Child Care in Poland, *by Maria Ziemska. New York, N.Y., Gordon and Breach, 1978, 148 pp., $16.75.*

This book is the eighth in a series of monographs on early child care in various countries, including Hungary, Sweden, the United States, Switzerland, Britain, France, and Israel. As the author points out in the introduction, it is essential that the reader have some knowledge of the history of Poland in order to understand the vast changes that have occurred there—the destruction of institutions and its effects, particularly on the family unit. The country was partitioned by Russia, Prussia, and Austria in the late eighteenth century, and these countries continued to influence Poland for many years. Some strides were made in unifying the country between World Wars I and II, but the latter war resulted in the catastrophic loss of some eight million Polish people, devastating families and leaving millions of children without parents. This book tells of the efforts to rebuild Poland in the context of a socialistic political system of government.

Some of the efforts have been more successful than oth-

ers. The state regulates most areas of life, including child rearing. Prenursery schools have been established for the care of infants up to three years of age so that both parents can work. Mothers can be given maternity leave with pay, and this is encouraged. There are nursery schools for children from ages three to six, and first grade begins when the child is seven. Attempts are made to give all infants and children adequate medical and psychological attention, but the author readily admits that there are many things yet to be accomplished. There is a shortage of personnel in some of the schools, but efforts are being made to train more professionals.

Throughout the book the heavy flavor of socialism is obvious. Nevertheless, the Polish people have a strong sense of the family unit and are attempting to provide for the physical and emotional needs of their growing children. There is a recognition that children who spend at least part of the time in their own homes do better than those who are full-time in almost orphanage-like care. Foster home placement and adoption are encouraged.

This book is not primarily aimed for the psychiatric reader. The author pays much more attention to maintenance of physical health and education than to emotional development. Although the book is not particularly well written, it should be of interest to those who want to know more about Poland and how the Poles are dealing with child rearing in the present social and political system.

STUART M. FINCH, M.D.
Tucson, Ariz.

Currents in Alcoholism, Vol. III: Biological, Biochemical, and Clinical Studies, *edited by Frank A. Seixas, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1978, 589 pp., $31.50.*

Currents in Alcoholism, Vol. IV: Psychiatric, Psychological, Social, and Epidemiological Studies, *edited by Frank A. Seixas, M.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1978, 487 pp., $26.50.*

This is the second set of volumes resulting from the annual National Alcoholism Forum jointly conducted in May 1977 by the National Council on Alcoholism and the American Medical Society on Alcoholism. These two volumes contain the work of 183 investigators reporting 76 studies.

As was true of the first two volumes, these are not books to be read cover to cover to find out all about alcoholism. Rather, they represent a unique opportunity for both new and veteran alcoholism investigators to share ideas and capture those ideas in print. As such, these volumes are important as markers of where we are trying to comprehend this very complex disorder.

There are four summarizing chapters for the project reports that follow. These are "Progress in the Study of Ethanol's Actions in the Brain" by Goldstein, "Progress and Perspective: Clinical Research in Alcoholism, 1967-1977" by Sellers, "Psychology/Psychiatry and the Alcoholic" by Schuckit, and "Social and Epidemiological Research" by Irgens and Jensen. Some bits and pieces that attraced my interest include the following:

Alcohol withdrawal is a central autonomic outflow, not a peripheral response. Exercise reduces alcohol consumption in rats. Would it do the same in humans? We are learning more about the effects of acetaldehyde on the mitochondria of the liver, heart, and brain, but we do not know why body manufactures aldehyde dehydrogenase in excess of need to metabolize internally produced alcohol. The amou of time it takes for the "zonk" effect from intoxication subside depends on the complexity and novelty of the ta A simple sweat test has been devised to determine if a p son has been drinking and how much. This could be an fective monitoring device. When we look for new agents reduce the severity of alcohol withdrawal, alcohol its should not be forgotten; it is safer than some drugs in curre use.

Alcohol increases feelings of self-worth in adolescents. 192 heroin addicts, 37% were also alcoholic. Nonverbal se sitivity in counselors correlates with therapeutic success. coholics presented with the fixed-interval drinking-decisi who chose not to drink did best on follow-up. A standa depression scale showed 66% or more of an alcoholic sam to be depressed, but clinical examination of the same sam revealed only 9% to be depressed. Drinking in the morn may be more related to severe depression than to addictic Alcoholics with high extraversion and neuroticism sco have lower tolerance to alcohol and show greater cogniti impairment. The Shipley Hartford is the best test for orga brain damage and demonstrates that recovery in the first days is not complete. There continues to be a belief that ducing total consumption of alcohol will reduce the numb of heavy drinkers. A first-time arrest of an adolescent possession of alcohol does not indicate serious problen but multiple arrests do. Alcohol use among high school s dents continues to rise slowly, but marijuana use is incre ing more rapidly. A study of a statewide treatment system Oklahoma showed that more costly programs do not tr the more impaired, as had been expected, and that there no evidence that greater cost leads to better results. Ear stage alcoholics are less likely to be abstinent than late-st alcoholics after treatment.

ROBERT A. MOORE, M.D.
San Diego, Calif.

The Child in His Family, Vol. 4: Vulnerable Children, *edit by E. James Anthony, M.D., Cyrille Koupernik, M.D., a Colette Chiland, M.D., Ph.D. New York, N.Y., Wiley-Int science (John Wiley & Sons), 1978, 660 pp., $25.95.*

The appearance of this volume is one more step in the pu lication of papers originally prepared for the 7th Congress the International Association for Child Psychiatry and All Professions held in 1970. The format and organization these volumes have been described in previous reviews the *Journal*. The opening paper, "A New Scientific Regi to Explore" by Anthony, was the Presidential Address the 1974 Congress.

Anna Freud sets a comfortable note in the prologue pointing out that the concept of vulnerability is the proce of development itself. A number of papers return in one w or another to this theme, stressing the critical relationsh among origin, life process, family relations, and commun activities in the life of the child who has difficulty in copi Anthony's paper actually sets forth a covert ambivalence our society: "In the child rearing methods, we are rais children who no longer care to rear children." This proph ic statement is related to the interactions in the family str ture that will beset the child of the future.

The groupings made by the editors include the physi

spects of vulnerability, the psychodynamic approach to ulnerability, the vulnerable infant, vulnerability and parent, nd a fascinating series of papers titled "Vulnerable Chil-ren of Madness." Continuing the theme, another section oncerns vulnerability of the disadvantageous environment nd, finally, the life history of the vulnerable child.

Preventive measures in vulnerability serve to conclude the olume with a return to the theme in Solnit's "Retrospect on ie Vulnerable Child." His paper points out the need for in-reasing the maximum potential of the family in the commu-ity. He notes, however, that at times a regression through lness may provide a moratorium so that the continuity of fect in the environment can provide a critical renaissance f the child's worth as opposed to his vulnerability. His com-ient, "Bringing up children is not the same as preparing iem for life," is a note included in a variety of the papers.

I found certain papers more exciting than others. A pithy aper by Erlenmeyer-Kimling concerning research focuses matched by an excellent paper on the long-term rehabilita-on of the retarded by Clark and Clark. Yvon Gauthier's udy of the fantasy life of vulnerable disadvantaged children early describes a background of the need for care with iese children. Two articles, one by Park on the positive val-e of parents and another by Brown on positive outcomes of are, set a tone rather different from the many studies of the ifficulties children face. Moreover, some of the papers in ie life history section include optimistic follow-ups.

For those of us who worry about small children, the de-cription of an excellent preschool program by Vaughn and ssociates is clear, realistic, and well-formulated as a teach-ig program. The entire section on vulnerability and mad-ess offers not only clinical pictures but some serious guide-nes for the clinician dealing with the problems of children ving in families in which mental illness is an environmental iven. Bruno Anthony, for example, notes that children of ianic patients have considerably fewer psychological in-olvements with their parents but that the children of schizo-hrenic patients get locked into the illness process; the out-ome of the process is thus altered by the child's interaction.

Studies of this sort point the way to experiments in care nd are supported by Bohman and Sigvardsson's 18-year udy of adopted children. Their feeling is that adopted chil-ren fared better in many instances than other children laced in foster homes or left in difficult home settings.

The epilogue by Mahler should not be neglected. As one ight expect, she uses the theme of separation and ties it to ulnerability. Her short paper is a biography pointing out the mely value of transitional phenomena as well as of separa-on in providing a moratorium (like the "fallow year" theo-y) that enables one to reorganize one's talents, take advan-ge of one's anxieties, and go forward in a positive fashion.

HENRY H. WORK, M.D.
Washington, D.C.

epot Fluphenazines: Twelve Years of Experience, *edited by rank J. Ayd, Jr., M.D. Baltimore, Md., Ayd Medical Com-unications, 1978, 160 pp., $15.00.*

Frank Ayd organized an international symposium on de-ot fluphenazines at the Sixth World Congress of Psychiatry i Hawaii. The proceedings of this conference are published i this monograph. The papers focus on a common theme in n interesting and convenient package of scientific informa-ion that provides an update on the progress of maintenance treatment with depot neuroleptics. Indeed, I cannot help but note that these interesting and clinically relevant papers satisfy the criteria for a good continuing medical education program. Because maintenance treatment is so widespread and important this book is of value to any psychiatrist, but it is particularly important for the clinician who is involved with the long-term treatment of patients suffering from chronic illness.

Several authors discuss their clinical experience (e.g., Donlon, Imlah, Marriott, and Heinrich). Docherty provides analysis of the studies on the degree of prophylaxis of depot medication compared with placebo or oral drug. He calculates the percentage of relapses on depot drug and divides this by the percentage of relapse on placebo or on short-acting oral drugs. He calls this index the prophylactic effect or PR index. I have a theoretical disagreement about his use of the percentage of patients relapsing. There is conceptual merit in asking whether the rate of relapse of patients on maintenance drugs or placebo is constant over time (1). As patients relapse, they are dropped from the study; obviously, then, as there are fewer and fewer unrelapsed patients, the number of unrelapsed patients is continually shrinking. This introduces an artifact in using the number of patients relapsed or the percentage of patients relapsing.

The clearest comparison of depot intramuscular versus oral drug is provided by three controlled studies. In a careful study Rifkin found essentially no difference between oral and depot fluphenazine. This finding is supported by a recently completed NIMH double-blind study (2) that found the depot drug to be equal to the oral. The other two studies reported in *Depot Fluphenazines* found that the depot drug was superior to oral fluphenazine, a finding supported by the natural history studies. One possible explanation for this discrepancy would be that some studies focus on patients who have a history of not taking their medication. In these cases depot fluphenazine would have a real advantage. Other studies may have a population of patients who take oral medication with good compliance. Docherty finds that depot fluphenazine is more beneficial in comparison with placebo than oral drug. However, the studies with depot drug generally lasted for 6 to 9 months, but the studies of short-acting drugs often took 24 to 48 months. Use of percentage relapse may create an artifact here. Even so, the general trend of the results suggests that depot fluphenazine might be better than oral maintenance medication.

Leff reviews the combined results of studies of the families of patients receiving maintenance drug or placebo. Relapse occurs in patients who come from families in which there is a high degree of expressed emotion (e.g., critical comments, hostility, and emotional overinvolvement). This obviously opens up an important lead for future investigations. It appears that some families are more successful at keeping their family members out of the hospital than others. If the interpersonal psychosocial supports of these families can be elucidated, these principles could be applied to families who do not do it naturally.

There is much information of real substance in this volume. These carefully collected hard data are needed as grist for an interesting methodological critique. If only clinical anecdotes were included, there would be little to say. This volume has the special merit of providing a good continuing educational program. It has a coherent educational purpose in that it deals with the practical and important clinical question of depot medication and has a number of high quality papers presenting data and opinions about this clinically important issue. It is a book that must be read by physicians dealing

with chronic schizophrenic patients. I would give it an excellent recommendation.

Law and the Mental Health Professions: Friction at the Interface, *edited by Walter E. Barton, M.D., and Charlotte J. Sanborn, A.R.T. New York, N.Y., International Universities Press, 1978, 319 pp., $15.00.*

This book is the product of a conference held at Dartmouth College in August 1976. The contributors are a distinguished group of lawyers and mental health professionals who have been active at the interfaces of law and mental health systems. The staggering escalation of legal activism in the mental health field is borne out by the estimates of attorney Bruce Ennis of the American Civil Liberties Union in his contribution. Ennis states that in 1971 there were about 10 lawyers with "substantial training and experience in representing mental patients in test case litigation," whereas in August 1976 there were "more than a thousand" such lawyers. He estimated that in 1976 there were 300 test cases being litigated on the rights of patients. This represents an enormous involvement of both lawyers and mental health professionals in legal proceedings, particularly in public mental health areas. Despite all this activity, Zigmond Lebensohn observes that "there is little evidence that this legal attention has done mental patients much good."

There are 13 chapters in this book devoted to 6 substantive legal issues: Recent Court Decisions and Practice, Informed Consent, Malpractice, Confidentiality, Competence and Responsibility, and Patient Rights and Involuntary Admissions Limited to Dangerousness. Two or three authors present differing points of view in each of the 6 areas. This creates a mildly adversarial structure, but these are all men and women of goodwill who can be characterized as trying to reason together over major controversies that are currently unsettled and unsettling. There is anguish but no acrimony. The lawyer contributions (6 of the 15 authors and co-authors) are all experienced in communicating with the mental health professions and in general are lucid and not overly legalistic in their presentations.

The chapters are superior for the most part, but there is a range from excellent to average. These proceedings were ambitious in scope and complexity of the issues confronted. The book is certainly worthwhile, at the very least as an updating of the evolution of important areas that affect mental health practice. To a degree the authors presage what is coming as well. In particular, informed consent to treatment appears to loom as the newest escalating conflict between the two professions. Private practitioners will not be excluded from legal actions involving this vexing issue.

There appear to be glimmerings of at least empathy and some understanding between the disciplines in this work. For example, attorney Bruce Ennis acknowledges that test case litigation is at best a "blunt instrument." Perhaps such efforts as this book represents, in which reasonable men women gather and communicate in good faith and with tual education across disciplinary lines, will lead to gr equity for all, not the least our patients.

Ethological Psychiatry: Psychopathology in the Context Evolutionary Biology, *edited by Michael T. McGuire, M. and Lynn A. Fairbanks, Ph.D. New York, N.Y., Grune Stratton (Harcourt Brace Jovanovich), 1977, 219 p, $15.00.*

Ethological studies of animal behavior begin with obser tions of animals in their natural environment. From the observations hypotheses are derived that are experimenta tested. During testing, variables are systematically manip lated to determine the immediate causes and consequenc of behaviors, how behaviors are organized, and how th appear, change, and disappear over time. Hypotheses abc a behavior's adaptive functions, either in the present or the species' evolutionary past, are usually part of a final e planatory scheme. Abnormal behaviors are viewed agai the background of corresponding normal behaviors, a adaptive functions of even pathological behaviors are cc sidered.

Ethology (originally a branch of zoology) and comparati psychology have become increasingly indistinguishable, a the arch-Skinnerian view of animal behavior as infinite plastic is now rarely encountered. Members of any speci learn some behaviors easily and others only with extrer difficulty. Study of the lives of animals in their natural en ronments (as opposed to study of behavior in a Skinner bo often explains why.

Whether ethological theory can validly be applied to th study of human behavior is currently controversial. Are h man lives so variable across and within societies and shaped by learned and nongenetically transmitted langua and culture that evolutionary considerations are m leadingly irrelevant? Sociobiology, a logically and historic ly related subfield of ethology, relates behaviors to the cc

)t of inclusive fitness, the idea that evolutionary pressures not on individual organisms competing against all others on individuals who bear genes that they share in increasly diluted fashion with increasingly distant relatives. To ciobiologists, altruistic acts function to increase the sural of one's own genes. Again, to what degree language l culture emancipate humans from selection pressures opting in this way is hotly and acerbically debated.

f ethology and sociobiology are applicable to human be-vior, they are potentially highly relevant to psychiatry. e evolutionary history of our species ultimately provides source of Freudian drives, Jungian archetypes, and Adan strivings for power. If an evolutionary perspective can shown to be relevant to the understanding of human be-vior, it can provide a framework for reconciling these and er apparently conflicting conceptualizations of the ultite well-springs of human activity. Further, even if human iavior is so culture-determined that evolutionary considtions cannot add to our understanding of it, ethology's phasis on observing behavior in natural contexts (in con-st to psychiatry's traditional predilection for self-reports behavior) is still welcome. The methodology for such obvational work on problems of human behavior is becomincreasingly refined.

For these reasons, *Ethological Psychiatry* is a valuable ntribution. Its 10 chapters focus on the study of human iavior, especially theoretical issues. Three chapters are eral and theoretical, 3 deal primarily with models of psyatric dysfunction, 2 discuss the behaviors of psychiatric ients in psychiatric settings, and 2 discuss the implicais of ethology for psychotherapy. Without exception, the lity of the papers is high. They reflect each author's derstanding of the current state of the field. Most contribrs acknowledge that knowledge of the ethological paramrs of human behavior is still rudimentary, but a few sugt more certainty about the true nature of psychopathologstates than the data presented and cited warrant. The ok also offers critics of the position it exemplifies a numof easily assailed targets, e.g., the implications for psytherapeutic practice suggested by a few contributors will ke even sympathetic psychiatrists as unsupported.

thological Psychiatry delineates an evolutionary perctive of behavior and discusses the issues involved in lying behavior by direct observation. As such it will be ful to psychiatrists who have been looking for an orgaed exposition of the salient issues in ethology and their ential relevance to psychiatric theory and research.

dc Principles and Techniques in Short-Term Dynamic Psytherapy, *edited by Habib Davanloo, M.D. New York, V., SP Medical & Scientific Books (Spectrum Publtions), 1978, 549 pp., $30.00.*

This book is a summary of the proceedings of the First and ond International Symposia on Brief Psychotherapy held Montreal in 1975 and 1976. It features the work of Peter neos, D.H. Malan, and Habib Davanloo, but there are alcontributions by Judd Marmor, Hans Strupp, and others.

The principal authors are psychoanalysts, and their chief pose is to demonstrate the fruitful application of psychoalytic principles to brief psychotherapy. They wish not only to show the effectiveness of this form of treatment, to which they are strongly committed, but to explore its limits. In their view (and most outspokenly in the writings of D.H. Malan), brief psychotherapy is not simply supportive help for relatively healthy persons who find themselves in a situational crisis. The authors feel that, through the application of analytic principles, brief psychotherapy can produce significant character changes and deal with issues at the core of the personality rather than just with the more superficial aspects of adjustment. Malan also feels that analytic brief psychotherapy can be applied with great benefit to patients with serious neurotic difficulties as well as to those with milder problems.

Each author approaches the patient in his own characteristic fashion. Sifneos, for example, often uses confrontation and anxiety-provoking questions, while Malan emphasizes interpretation of the transference and the technical importance of linking it with childhood. They have in common a psychoanalytic orientation and a very active therapeutic style designed to help patients focus on what seems clinically most relevant at the moment.

Does brief psychotherapy regularly accomplish what the principal authors believe it accomplishes, or are major changes and personality restructuring during short-term treatment more a matter of serendipity, as Marmor suggests at one point in the discussion (p. 189)? The reader will be able to draw his or her own conclusions because one of the very positive features of this book is the generous use of clinical material and the openness with which it is presented. More than a dozen interviews are reported verbatim, and the reader has the opportunity to observe how the patient is approached and the material developed. The skill of the therapists is very evident, but I also got a sense that, to make time count, they try almost too hard to acquaint the patient with his fundamental dynamics. Thus, for all the emphasis on interpretation, their interventions often seem more educational than truly interpretive. They are inclined to explain and point out to the patient what his unconscious contains rather than facilitate the progressive clarification and unfolding of emerging preconscious material. Therefore, insight is seen more as something imparted to the patient than developing within the patient as constricting defenses are gradually loosened. In keeping with this stance, not much is said about the role of working through and the limitations that time constraints inevitably place on brief psychotherapy.

Perhaps the book's weakest link is the review of the literature, which does not quite do justice to the topic. There is also a tendency throughout to treat the contributions as "new" even though they deal with issues that have been in and out of the psychoanalytic literature consistently, particularly since the work of Stekel, Rank, and Ferenczi. These caveats aside, this is a useful book that combines solid material and a thoughtful presentation with a dash of controversy. It will be read with interest.

Psychopathic Behaviour: Approaches to Research, *edited by R.D. Hare and D. Schalling. New York, N.Y., John Wiley & Sons, 1978, 378 pp., $32.00.*

This book contains 20 chapters that are revised versions of papers presented at an international conference on psychopathic behavior held in Les Arcs, France, in 1975 and sever-

al additional chapters written later. The conference was supported by the Scientific Affairs Division of NATO and attended by people from 13 countries whose areas of interest were in psychology, sociology, psychiatry, psychophysiology, genetics, criminology, and corrections.

The authors write in a condensed, tight style and add a long bibliography to each chapter. Because of the complexity of the presentation, with reviews of controversial points and tentative hypotheses, I shall present only a small portion of the material with the hope of conveying its value. The book is a must for serious students of psychopathy.

The first 3 chapters discuss the concepts of psychopathy, sociopathy, and antisocial personality. Lack of clarity in these concepts makes for major problems in the selection of both psychopathic and control subjects for research. For example, a commonly used source of psychopathic subjects is the prison, but is the prisoner a special subtype of psychopathy? What psychological dimensions are appropriate for control subjects?

The excellent fourth chapter presents a historical overview of the concept of psychopathy. At the present time there is a basic difference between the concept that describes a type of personality defined by its social maladjustments and the concept that includes abnormal personalities defined by deviation from normality and by making either the subject or society suffer.

Chapters 5–11 are chiefly concerned with methods of studying psychopathic subjects or the application of particular techniques to investigate specific dimensions of psychopathy. For example, in one study psychopathic subjects were recruited for research by the following newspaper advertisement: "Wanted charming, aggressive, carefree people who are impulsively irresponsible but are good at handling people and looking out for number one." The subjects who answered were found to be similar to prison subjects in most ways, including a high frequency of arrests, but they differed in having a low frequency of convictions.

Chapters 12–15 discuss genetics and psychopathy. The concordance rate for criminality in 9 twin studies was 55% for monozygotic twins and 13% for dizygotic. Adoption studies show that psychopathological adoptees have a higher percent of psychopathological relatives than nonpsychopathological adoptees. Studies of children who later become psychopathic reveal an excess of stealing, incorrigibility, truancy, running away from home, discipline problems in school, and school retardation. Parents with a diagnosis of antisocial personality produce more children with behavior problems, but broken homes, association with bad companions, and social class alone do not seem to have much influence on creating psychopathy.

Three chapters deal with psychopathy, criminality, and delinquency. Internal controls are regarded as factors that inhibit criminal behavior. There is evidence that parents who emphasize motives or intent are likely to build in their children a greater resistance to temptation to break societal rules. The unprincipled opportunism of the psychopathic person is his tendency to exploit people and the system. This contrasts with the socialized person who says, "I would never have thought of doing a thing like that." Some workers believe that teaching parents how to reinforce desirable behavior and how to be better parental models themselves may reduce juvenile delinquency.

A final chapter concerns treatment. A widespread view is that no demonstrably effective treatment for psychopathology exists, but many believe that if the psychopath lives in a situation where firm but not oppressive rules are enforced and his manipulative attempts are unsuccess some benefit may follow. Milieu therapy may also help. alternative is the institutionalization of the psychopath u he has reached the age when most "settle down," usu between 30 and 40. A quotation from Aubrey Lewis repea by a writer of one of the chapters seems apropos here:

> The conclusion of the whole matter is somewhat gloor The diagnostic groupings of psychiatry seldom have sh and definite limits. Some are worse than others in t respect. Worst of all is psychopathic personality w its wavering confines. Its outline will not be firm u much more is known about genetics, psychopatholo and neuropathology.

Clinical Uses of Dreams: Jungian Interpretations and Enr ments, *by James A. Hall, M.D. New York, N.Y., Grune Stratton (Harcourt Brace Jovanovich), 1977, 350 p \$22.50.*

Clinicians who are disenchanted with classical Freud interpretation of dreams and yet are convinced of the imp tance of dream interpretation will find this book of con erable value. It deals with the largely neglected but extrer ly important clinical contributions of C.G. Jung to dre theory and interpretation. Although Jung more or less a avowed "theory" and spoke of empirical facts, his phen enological observations and ideas are appropriately pla by Dr. Hall in the form of theory in order to compare it w others.

The book begins with a history of dream interpretat from antiquity to Freud and explains the various other th ries and the laboratory study of sleep and dreams, examin the latter from both Freudian and Jungian perspectives major thesis of the book is that Jungian dream interpreta rests not only on the personal unconscious but also on potential of the collective or objective unconscious for h ing by its creative and synthetic functions.

Classical Freudian theory emphasizes the reductive defensive analysis of dreams as disguised repressed unc scious wishes. Jungian theory postulates that dreams are unconscious compensation for distortions of consciousn the dream having a guiding prospective function. Class Freudian theory interprets the hidden, latent dream be the facade of the manifest dream. Hall points out that Ju ian theory postulates that the so-called manifest dream is actual dream and there is no latent dream. Free associa is a technique that takes one away from the "disguis dream. The Jungian technique of amplification of dream ages, with meticulous attention to all dream images, ke the emphasis on the dream itself. Hall notes that the s regulatory or compensatory function of the dream does imply teleology but a movement toward wholeness and i viduation.

The author's theory of the dream ego and its relation to the waking ego is a particularly valuable clinical const allowing distance and perspective. Despite all theories, I correctly recognizes the basic art of dream interpreta and its essential subjective nature. This is an inescapable ment in the science of clinical dream interpretation.

The brief chapter on Polyani's tacit knowing theory se to be an attempt to bridge a gap with a controversial, brill

ory. It adds nothing to the book. Perhaps it might have n replaced by a longer chapter on enactments, the dis-sion of which is relegated to the last 17 pages of the book. it is hardly enough space to do justice to painting, sand-work, imaginal techniques, guided imagery, active gination, dance, art, and poetry. Still, in all, Dr. Hall naages to give considerable balance, scope, and depth to g's ideas in this book, from typology to the central arche-e of the self from which dreams are said to come. As an oduction to Jungian dream interpretation this book is hly recommended.

HARRY A. WILMER, M.D., PH.D.
San Antonio, Tex.

nce and Treatment: Clinical Uses of Hypnosis, *by Herbert egel, M.D., and David Spiegel, M.D. New York, N.Y., ic Books, 1978, 370 pp., $18.50.*

ne of the stated goals of this interesting volume by Her-t Spiegel and his son David is "to make clinical experi-e with hypnosis more systematic by using measurements have evolved during the past decade." Among the basic positions presented are that trance capacity and depth stable characteristics that are bracketed to distinctive sonality styles and that assessing hypnotizability is diag-tically important because it facilitates the choice of treat-nt method. The authors emphasize that one of the diffi-ies in psychiatric practice is coordinating the methods of tment with the problems and personalities of patients king help. Clinically assessing hypnotizability works to-d resolving this problem by "helping the clinician to e a better match between patient and therapist."

o achieve this objective a rapid clinical assessment pro-ure, the hypnotic induction profile (HIP) is recommended crucial in our evaluation of a patient for treatment." The is an easily learned, rapidly administered induction pro-ure that permits an estimate of trance capacity. In con-t to the Stanford Hypnotic Susceptibility Scales and the vard Group Scales, which require a long, arduous period duction, the HIP takes no more than 5 to 10 minutes. An nious score sheet facilitates recording of responses. e the HIP has been obtained and scored, self-hypnosis be readily taught the subject so that he can apply strate-consonant with his trance capacity. The HIP technique xcellently presented and illustrated, and the reader can n it without great difficulty. Obviously, expertise in the hod requires a good deal of practice.

he authors attempt to substantiate the relevance of the to psychopathological syndromes and personality quali-by presenting clinical and research data. Drawing on ek mythology, they depict three personality styles: Dio-ians, who display high hypnotizability scores and mani-extensive psychological dysfunction, role confusion, a fixed sense of inferiority; Apollonians, who show low notizability, are organized and critical, and whose con-and reason dominate passion; and Odysseans, who are nid-range hypnotizability, subject to alternative moods, function between reason and feeling. The authors con-l that their typologies may be of help in adapting tech-ues to patients' personality styles.

here is a good deal of controversy surrounding the issue he relationship of hypnotizability to psychopathological dromes. The authors present some challenging opinions emerged from their work with the HIP. Schizophrenic patients and those with obsessive-compulsive disorders are not the best of subjects, but hysterical and highly suggestible people are traditionally presumed to be the most hypnotizable. These facts come out in the scores obtained by the authors in the HIP. However, is the reason for this inherent in the syndromes themselves, as the authors imply, or in such adventitious factors as inability to fix attention, distrust, fear, and distortion of reality present in many schizophrenic and obsessive patients, contrasted with the needs for fusion and other motivational forces that make many hysterical patients peculiarly susceptible to suggestion? Clinical experience validates the ability of schizophrenic patients to enter trance states once they have established a trusting relationship with their therapist, and some of the most resistive subjects are hysterical patients who regard a hypnotic relationship as a threat. By and large we are far from possessing definitive answers regarding the connection of hypnotizability to diagnostic categories because good and bad subjects spread themselves over the entire spectrum of psychosis, borderline personality, neurosis, and character disorders.

Another debatable issue in hypnosis about which the authors take a definite stand is whether or not hypnosis is a stable and reliably measurable trait. They suggest that hypnotizability remains the same under all or most situations. There is no true clarification of this issue in the book. The HIP would seem to lend itself admirably to testing the authors view by using it with patients and voluntary subjects under changing circumstances over a sufficiently prolonged period of time. Particularly important would be a study of the effect of different therapists and operators on HIP scores. Moreover, using several induction methods in addition to the HIP would be valuable to see whether patients respond better to some techniques than to others.

The chapter on research findings is inconclusive because the studies presented possess serious methodological flaws. The first informal study involves the prediction of personality typology on the basis of psychological test batteries. Without knowledge of who did the tests, it is impossible to know whether the batteries were comparable. Interrater reliabilities of predictions were also quite low. Moreover, we are not given the criteria on which group judgments were based. Even though these judgments were statistically significant they were not meaningful because they accounted for only 10% of the variance, which the authors themselves note. The investigations focused on the HIP are also unpersuasive because of methodological flaws. In the report on the relationship of low HIP profiles to severe psychopathology, criteria for assigning patients to the health-sickness scale are not specified, and the sample was small. The authors' conclusion from these minimal data that HIP predicts psychopathology simply cannot be drawn from the slight evidence that the two are weakly associated. This is a common error in interpreting the results of positive correlations, which can never be taken as indications of causation.

The last section of the book, by contrast, is excellent. It contains innovative strategems for the control and treatment of a number of conditions, including smoking, obesity, anorexia nervosa, anxiety, concentration problems, insomnia, phobias, pain syndromes, psychosomatic disorders, conversion symptoms, and behavior disorders. These topics are discussed in detail with a good deal of clinical acumen. This section in itself makes the volume a worthwhile addition to the library of any psychotherapist.

In summary, the authors deserve commendation for writing a book that is provocative and challenging. Although the

questions the authors attempt to answer with their clinical and research data regarding hypnotizability as a diagnostic tool, as a means of matching patients and therapists, and as a way of identifying preferred treatment methods are by no means resolved, they offer hypotheses that open up a fertile area for future research. The well-presented HIP is a practical, rapid, easily scored hypnotic method, and the pointers regarding techniques and the phrasing of suggestions for a variety of conditions are valuable.

LEWIS R. WOLBERG, M.D.
New York, N.Y.

Inheritance of Creative Intelligence, *by Jon L. Karlsson, Ph.D., M.D. Chicago, Ill., Nelson-Hall, 1978, 200 pp., $14.95; $7.95 (paper).*

Jon Karlsson has made some important contributions to the genetic study of schizophrenia, applying pedigree and adoption strategies to a population in Iceland. In this book, however, he deals not with the genetics of mental illness as such but with some intriguing hypotheses that, on the genic level, associate intelligence with myopia, creativity with schizophrenia, and giftedness or leadership with alcoholism. As speculations stemming from accepted evolutionary considerations and various biographical and family data, these hypotheses do not lack interest and may serve to spur further research. In the evolutionary sense the concept of selective advantage for gene carriers has been established for sickle-cell disease, and there have been attempts to apply this model to psychiatric illness, especially schizophrenia. However, Karlsson, in his more polemic passages, writes as if his particular hypotheses were proven facts and draws conclusions for social action whose consequences would be serious indeed.

These conclusions may be summarized by the author's questions, "Can society tolerate more mental illness in order to have increased creativity? Should man sacrifice his visual acuity to raise the overall IQ level? and Should alcoholics be supported and their reproduction be encouraged in order to have more effective leaders?" (p. 173). Karlsson also states, "It appears that abundant creative intelligence can be provided only by acceptance of a corresponding increase in mental illness, alcoholism, and myopia" (p. 173).

The book is interlaced with much expressed bitterness toward the psychiatric and academic establishment for what the author considers its antiscientific, antihereditarian bias in apportioning funds for research. To me, certainly not unaware of such trends, this is an anachronistic view of how genetics is favored in United States research psychiatry today. (Contrary to Karlsson's statement on page 129, for example, NIMH does have a unit on psychogenetics.)

There are good and balanced presentations in this book of important topics in population and biochemical genetics. Discussions of the genetics of major psychotic illness are generally informative, although they give little attention to polygenic models involving liability thresholds. The material on mental illness is influenced by the author's opinion that schizophrenia and manic-depressive psychosis are overlapping disorders with many features in common and difficult to separate for purposes of genetic study. This viewpoint also colors the descriptions of mental illness in creative individuals and their families.

Those who wish to explore the author's theories further ought to read this book. References are listed in the back by chapters, but unfortunately some of them are hard to tr down because they are not keyed to the text.

This monograph, in short, is an idiosyncratic essay, of acrimonious and crusading in tone and controversial e among geneticists. It is certain to stimulate the intellectu curious but surely is not an introduction to behavioral netics for the uninitiated.

JOHN D. RAINER, M.D
New York, N.Y

A Grammar of Dreams, *by David Foulkes. New York, N. Basic Books, 1978, 441 pp., $20.00.*

In this book Foulkes allies himself with Freud in the m positive sense. Both are students of the mind who use dream to illuminate the workings of the mind. The choice the dream is based on the idea that the dream is the mer activity most free of external stimulation and dominance therefore the purest example of mind function availat Foulkes describes a scoring system for latent struct (SSLS) for coding or summarizing manifest dream cont and its free associations. He intends the SSLS to be a "n ful" approach to the interpretation of dreams and to the velopment of a reliable model of the process of dreamin

He provides a lively and compelling background for cognitive-linguistic synthesis of dreams in his review of conceptual base for a contemporary model of dreaming of the empirical resources available for his synthesis fr work in dream psychology and waking symbolic behav He closes with a very brief glimpse of the potential impli tions and applications his method has for clinical and exp mental dream psychology.

Foulkes argues that a cognitive-linguistic approach dreams captures the best insights of Freud's model of dre formation and his method of dream interpretation. Foul accepts Freud's views as the best approach to the dream dreaming. Importantly, he recognizes that nonmenta models (e.g., "asemantic neural approaches" [1]) cannot dress the central issues in dream psychology and miss point of Freud's contribution.

In SSLS each "sentence" in the dream and in the f associations is coded into seven relational and nine subj categories guided by Hornian and Freudian principles relationship and significant others. These codes are t built up according to very explicit rules to provide a comp interactional network to which a specialized mathemati analysis is applicable. The potential for mathematical an sis opens the possibility for mathematical tests of such c cepts as distortion, displacement, and condensation. The sence of the approach is the avoidance of the arbitrary.

Foulkes belabors the sterility of modern dream resear His assessment of the contribution of modern dream search is debatable and worthy of a separate essay. I h peripherally explored this topic in another context (2).

The work presents a well-grounded and explicit appro to the interpretation and construction of dreams and perh of the mind as well. It is helpful to understand that priv meaning is not the only goal of dream psychology or of approach. Further, the function of the dream, which is concern in dream psychology, is unlikely to be addressed this approach.

Unfortunately, I have a number of major concerns ab the approach. For example, there is no serious empirical plication of this methodology to encourage us to accept

e crucial mathematical methodology is presented so ab-actly that I could not understand it. The circularity of free sociation as a method to explicate dream formation is ted but not adequately addressed. The limited attention en to the affective or dynamic component in favor of the gnitive is regrettable. Lastly, the author's use of nonas-ciative explanations in rule making and his rejection of am-fication techniques require further discussion and testing. This book would be valuable for the student of the mind l for the student of the dream. For the most part, it is a del of how to write a book that integrates the necessary torical and intellectual background to properly present a w contribution.

radox and Counterparadox: A New Model in the Therapy of Family in Schizophrenic Transaction, *by Mara Selvini Pazoli, M.D., Luigi Boscolo, M.D., Gianfranco Cecchin, D., and Giuliana Prata, M.D.; translated by Elisabeth V. rt. New York, N.Y., Jason Aronson, 1978, 186 pp., .00.*

n this compact and readable book Dr. Palazzoli and her ee co-authors from Milan, Italy, present their work with izophrenic patients and their families. The text is com-sed principally of clinical examples of their method of aking up pathological equilibrium in the family by pre-ting "prescriptions" of counterparadoxical intent. The ily paradox is diagnosed and countered. Their theoretical mework borrows heavily from the work of Watzlawick, kson, and Bateson. The book is more meaningful if those lier writings and concepts are familiar to the reader. Inter-ingly, the bibliography cites no Italian sources other than authors.

Dr. Palazzoli first wrote in Italian 10 years ago about her lytic experiences with anorectic patients and their fami-s. She then turned to working with schizophrenic patients l their families and, with a team of two men and two wom-evolved the techniques described in this book. The anal-s of family interaction are astute. The interactions are lu-ly described. The "prescriptions" are delightfully inge-us and creative. At times one feels the team is utgaming" the family game playing—as indeed they are. One comes away from the book realizing again that it is easy to work with families. Nothing can be taken at face ue. Nothing is as it seems. To keep the family system in ilibrium family members behave in "pathological" ways. at appears to be reality is often not in terms of communi-ion theory. One of the remarkable accomplishments of team in communicating with the families is their ability to ue interpretations of behavior with positive constructive rtones: "You are being generous and giving to your ther by acting crazy." In less experienced hands the tech-ue could be dangerous and destructive.

The reported results are remarkable. The families showed marked improvement after only a few interviews. The families were seen once a month or at even longer intervals 10 times. Very occasionally the team extended the therapy to 20 sessions. Termination was then absolute. This book is valuable reading for any student of family interaction and therapy.

Gainesville, Fla.

Normal Psychology of the Aging Process, revised ed., *edited by Norman E. Zinberg, M.D., and Irving Kaufman, M.D. New York, N.Y., International Universities Press, 1978, 277 pp., $15.00.*

This revised edition includes the proceedings of the 15th anniversary symposium of the Boston Society for Gerontologic Psychiatry. The first edition presented the proceedings of the first symposium. The views of Zinberg, Kaufman, Goldfarb, Berezin, Linden, and Levin on cultural and personality factors, psychosocial and sociophysiological aspects, and intrapsychic and psychodynamic considerations are well expressed, stimulating the reader to agree or disagree with the formulations presented.

The discussions of regression, recession, and libido equilibrium in the psychoses of the aging point to the differing viewpoints of psychoanalytic interpreters. The semantics of regression, object loss, dependency, and libidinal gratification are interpreted with clinical examples.

Parts two and three focus on marital adaptation and a review of current studies on sex and old age. The authors regret that adequate information is not available for determination of the effects of aging on sexuality and the psychological implications of these effects.

I found the book provocative in that some authors' interpretations of clinical examples seemed based on psychoanalytic theory to the exclusion of the physiological changes of aging. For example, Kaufman interprets the hysterialike behavior of an over 70-year-old woman in a beauty parlor as resulting from the "timelessness of the unconscious expression of id derivatives," pointing out that "fear of rape and other sexual and aggressive fears and wishes can occur at all ages." I could not accept this formulation without information about what had been recent fears of this woman. My concern is that such interpretations of intrapsychic dynamics are written as though the student should accept them as fact rather than using formulations to explore alternative bases for what is apparently irrational behavior.

The list of current references provides a source for further reading and points again to the multifactorial complexity of studies of the psychology of the aging process: the cultural, social, economic, physiological, and personality differences that make generalizations about aging individuals fictitious.

SHIRLEY M. COLTHART, M.D.

The Human Dimension in Psychoanalytic Practice, *edited by Kenneth A. Frank, Ph.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1977, 202 pp., $14.75.*

In 1947, Dr. Fanny von Hann-Kende, one of my supervisors at the Columbia University Center for Psychoanalytic Training and Research, remarked that she knew of only one

article on countertransference. It had been written in Hungarian in 1932 and had been translated into German but not into English. In the 1950s, there was a beginning recognition in the literature of the analyst as a thinking, feeling, perceiving human being—a live partner in the patient-therapist dyad. The therapist's internal reactions as well as some of his or her external actions were perceived as countertransference phenomena according to the models of transference and countertransference enunciated by Freud.

Despite some acknowledgment of the "human dimension" in the psychoanalyst in the 1950s and 1960s, there were still many proponents of the "blank screen" perception of analysts, an elite who were immune to the human frailties. However, Otto Will and Harold Searles, among others, have been unabashedly candid about their subjective thoughts and feelings as well as their behavior in the therapeutic setting. They have talked about human feelings and continue to do so, rather than characterizing their responses as countertransference phenomena. In the introduction to *The Human Dimension in Psychoanalytic Practice* the editor quotes Anna Freud in this context: "The analyst and patient are also two real people of equal adult status, in a real, personal relationship to each other." (1).

This volume contains 13 highly personal contributions by competent analysts with a variety of theoretical frames of reference. Searles's contribution considers the role of mature hope in the patient-therapist relationship as well as the role of the conflicting and contradictory hopes and fears in both patient and therapist. He enunciates the importance of the therapist's changing his or her perspective to keep it consistent with the data rather than focusing on the patient's earlier perceptions and expectations. He gives a thumbnail sketch of the first few agonizing sessions with his second analyst, noting how some of his fears were allayed and his hopes engendered. He had entered this second analytic effort after having been summarily dismissed early on by his first analyst.

Fairbairn and Winnicott were the two analysts with whom Guntrip spent time in successive analytic experiences. Guntrip responds to the query, "How complete a result does psychoanalytic therapy achieve?" by noting that theory "is a useful servant but a bad master. . . . In the last resort, good therapists are born not trained and they make the best use of training." Guntrip gives detailed accounts of some of his analytic experiences and his perceptions of the analysts' reactions during and afterward. He sees psychoanalytic therapy as the interaction of the personalities of two people working together toward free spontaneous growth. The analyst as well as the analysand grows. There must be something wrong if an analyst is static when dealing with dynamic personal experiences.

Ralph Greenson's "That Impossible Profession," first published in the *Journal of the American Psychoanalytic Association* in 1966, is included in this volume. The editor notes that Greenson, more than any other prominent orthodox American analyst, has delineated the issues of the psychoanalyst as a person and the real, human relationship between the analyst and the patient. In this paper he characterizes the analyst as having complex and antithetical skills, varied and contradictory traits, and motivations that are difficult to define. He concludes by stressing the crucial importance of a deep, personal, analytic experience and a good personal life outside of one's work. These can render the impossible profession not only possible but rewarding.

Certain patients intimidate their families, school authorities, and, on occasion, therapists. Hilde Bruch notes that the therapist's failure to recognize his or her own anxiety a anger and to deal with the behavior of the patient can sab tage treatment. She gives an example of destructive, agre sive behavior on the part of an adolescent and several e amples of patients with anorexia nervosa who tyrannized their weakness and frightening physical state. Some the pists have believed that resolution of the underlying conflic will bring about appropriate eating habits and weight gain. so doing they have avoided confronting the weight gain iss and the anorexic's intimidating behavior directly. Bruch approach is definitive and effective in neutralizing the tyra ny and restoring health. This includes confrontive measur that are sometimes life-saving, as well as recognizing not o ly the low self-image of the anorexic but also the tremendo power he commands through manipulating his environmen

Harold Kelman's presentation of his philosophy of ps chotherapy is a kind of valediction. He died at age 71 wh the book was in press. His article interrelates his persor and professional histories with his philosophy. He se every patient as suffering from a multidimensional feeling "nobody-was-there-for-me" during infantile development a consequence of distortion of organic modalities. The ta of the therapist is to help the patient to experience these m dalities in an undistorted fashion as well as to experience t therapist in multiple caretaker roles. Kelman elaborates e tensively on his technique, which provides responsivene to needs but avoids subjective involvement with the patien

This short volume is remarkable in the breadth, depth, a comprehensiveness of the articles and the candor and ope ness of the authors. Parts of it will certainly touch vibra chords in every therapist who is alive and growing in t "humbling profession."

JAMES P. CATTELL, M.D.
Pittsfield, Mass.

Child Behavior Problems: An Empirical Approach to Mana ment, *by Roger McAuley and Patricia McAuley. New Yo. N.Y., Free Press (Macmillan Publishing Co.), 1978, 233 p, $13.95.*

This small volume is easy reading for the psychiatrist w wishes to begin his or her understanding of behavior thera with children, now that some of the major differences tween behavior therapy and psychotherapy have started dissolve. The approach is clinically oriented and avoids technical language and statistical emphasis that often mal behavior therapy publications so uninteresting to the p chodynamically trained psychiatrist. Good comprehens and individualized history taking is the emphasis; this p vides another common guidepost familiar to the n behavioral clinician. It is clear that the McAuleys were ba cally good clinicians before they integrated behavior thera into their work. Although they emphasize externally obse able behavior, they do not ignore the internal life of youngster.

The underlying theory of the authors' concept of "appl behavior analysis" is that deviant behavior is developed a maintained by its short-term stimulus associations and t the discovery of these associations allows a reshuffling

v the stimuli operate. The emphasis on objective mea-
ement of behavior, especially overt and easily measur-
e behavior, sometimes appears dry and dehumanized be-
se it avoids cognitive and emotional factors, the internal
l interactional life of the youngster, that are not easily
asured. However, this approach adds an important di-
nsion to the good clinician's practice, e.g., having young
ents and their families keep diaries regarding certain tar-
symptoms or problems. Self-recording can produce an
reness of behavior that is a precursor to change.
he authors logically progress from data collection to
lysis of the data to planning and goal setting to implemen-
on of methods to assessment of progress in treatment.
y discuss basic theory and definitions, limitations and ad-
tages, and pros and cons and question the theory with a
l chapter on future directions and problems.
lthough the book is divided into three parts, Assessment,
nning, and Intervention, it could just as easily fall into a
-part division, which is the way it reads. The first is for
ents. The extensive use of parents and teachers as prima-
herapists is a characteristic of behavior therapy because
emphasis is on naturalistic settings. A discussion of dis-
ine that deals with the normal problems of everyday liv-
and point systems and contracts could profitably be read
parents whose discipline tends to be inconsistent.
he second possible division deals with clinical psycho-
hological disorders and the application of behavior thera-
o them. The authors provide case examples for such con-
ons as aggressive destructiveness, stealing, school refus-
stuttering, enuresis, and encopresis. Their balanced
roach is reflected in two case presentations of child
se, one of which was successful and one unsuccessful.
se help to tease out predictors and indications for behav-
therapy and are most instructive regarding limitations.
here is no reason why office psychotherapy, which al-
ly uses many of the techniques described in this book,
not be enriched and complemented by having patients'
ents use some of these techniques. The combined use of
ious forms of interventions such as psychotherapy and
avior therapy seems more and more possible and benefi-
to the young patient and his family.

JOHN F. MCDERMOTT, JR., M.D.
Honolulu, Hawaii

ality of Life in Severely and Profoundly Mentally Retarded ple: Research Foundations for Improvement, *edited by C. ward Meyers. Washington, D.C., American Association Mental Deficiency, 1978, 384 pp., $14.95.*

his monograph continues the high level of professional olarship and sophistication demonstrated in two previous lications of the American Association on Mental Defi-ncy. The papers are not addressed to physicians in gener-r even to psychiatrists in particular but primarily to those olved in the behavior and adaptive processes of the se-ely retarded.
he publication comes at a most opportune time for those rged with facilitating the adaptation of this population in community. There has been a marked increase in the ıber of these people in the community in the metropolitan w York area and presumably in most large urban centers ughout the United States. The professionals involved in habilitative process eagerly receive whatever new and ful techniques are suggested by reputable research re-sources and are ready to pursue them at the clinical level. Some innovative and stimulating ideas are contained in this monograph. Techniques for understanding and altering stereotyped behavior, level of involvement of parents in speech programs, other means of nonverbal communication, and extending the use of psychological tools (the Bayley Scales and others) for more refined definition and evaluation of the severely and profoundly retarded population are among others suggested.

The authors are not identified by title or profession but by affiliation with the university or institute where their research was carried out. Some have national reputations and are identifiable, but most are less well known; their backgrounds suggest predominantly behavioral and/or educational psychology, speech pathology, and special pedagogy.

These papers are carefully planned and designed, sophisticated in their use of data and statistics, and apparently rigorously executed. They are all well documented with extensive bibliographies. Regrettably, the publication itself leaves much to be desired. The print seems small and the lines crowded with barely any margin space for those addicted to making notes. Many of the tables were especially difficult to read. Although I believe the book will appeal only to the small audience particularly interested in the severely retarded population, those few may find some stimulating and rewarding ideas, perhaps even motivation for the further research suggested by the contents.

JOSEPH MICHAELS, M.D.

Videotape Techniques in Psychiatric Training and Treatment, revised ed., *edited by Milton M. Berger, M.D. New York, N.Y., Brunner/Mazel, 1978, 397 pp., $20.00.*

The use of videotape techniques is rapidly expanding in every area of psychiatric interest and expertise. The first edition of this volume was a welcome compendium of authoritative contributions to this expanding new field. This new edition is an attempt to bring us up to date on the rapidly expanding sophisticaation of technique and application, and it succeeds admirably in large measure. As John Spiegel states in his preface to the revised edition, "This is a 'how to' book, written by the growing number of technologically sophisticated therapists, trainers and researchers for those who are incipiently curious, definitely interested, while wishing to be instructed."

The book is organized into sections that deal with different aspects or applications of videotape technique. The first section deals with the technique of confrontation in psychotherapy. Although this section vividly portrays the technique of confrontation and reviews the considerable literature referable to this technique, little is offered in the way of outcome data either on its long-term efficacy or its ability to contribute to a shortening of the psychotherapeutic process. However, the case histories are well presented and to some degree convincing. The section on training is superb and brings together considerable expertise regarding the applicability of videotape to training in clinical psychiatry. The section by Herman Hirsh and Herbert Freed and that of Marsh Gowin and Frank Kline dealing with the use of videotape in supervision of psychotherapy are innovative and well structured. W. Douglas Weir's chapter on evaluating psychiatric learning through videotaped patient interviews is an excellent introduction to the use of videotape material for examination

purposes. However, it is limited in scope and does not include consideration of the utility of videotape-based examinations in program evaluation.

The section on treatment is fascinating because it focuses on the potential use of videotape in almost all forms of therapy, including narcotherapy, child psychotherapy, family therapy, group therapy with schizophrenic patients, marathon and encounter group therapy, individual therapy, and couples therapy. Almost all of the chapters are well written and easily understood. Again, the lack of comparative outcome data demonstrating a clear-cut improvement either in quality of outcome or decreasing length of treatment represents a limitation of the value of the contribution. However, one supposes this is a great deal to ask of an introductory text to a new and expanding field. Perhaps outcome data will be forthcoming.

The section on legal, moral, and ethical considerations presents model forms for signed release and attempts to deal with the issues of privacy and privileged communication as well as other legal implications and complications. Most of the germane issues are raised in a thoughtful way. There is an unfortunate tendency to view legal and ethical concerns over exposure of videotape clinical material as "legalism," but this is balanced by the broad view of the authors.

The final section, titled Technical and Artistic Considerations, should be of considerable help to any department of psychiatry planning or developing a videotape division. I particularly enjoyed the chapter on the technical and artistic aspects of videotape written by Harry Wilmer. One is too often exposed to videotape material that is fascinating in content but so poorly done as to be dull and aesthetically offensive.

This book is a valuable compendium of introductory information on the applications of videotape technique. To quote Lawrence Kolb's preface to the first edition, "As the educational and therapeutic applications of videotape expand and grow, we shall also expect its wider use in research concerned with human behavior." One would hope that some greater emphasis had been placed on research applicability and findings in the present volume, but it is a valuable contribution and recommended introductory reading in an exciting field.

ARTHUR T. MEYERSON, M.D.
New York, N.Y.

Alcoholism and Treatment, *by David J. Armor, J. Michael Polich, and Harriet B. Stambul. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1978, 343 pp., $16.95.*

Like a phoenix rising from its ashes the Rand Corporation report, originally published in 1976 as a monograph, returns in this volume, expanded with an 80-page index of the reaction to the storm of controversy generated on its first appearance. Its principal contribution will probably be the stimulus it gave to questioning established theory and practice. The authors, two sociologists and a psychologist, were not clinically involved with the subject population and had to rely entirely on prepared material for their statistical analysis and interpretation.

One need not in 1979 rekindle the fires that smoldered three years ago. The interested reader may wish to consult the local and national press of the time or, more succinctly, review the well written and fairly extensive apologia found in Appendix B. In spite of the methodological shortcomings inherent in self-reporting of drinking behavior and in data that are often haphazardly collected and recorded, this follow-up study is one of the largest of its kind, even though it involved a small number of subjects (14 of a group of 25). Its three major findings are worth noting, if only for the reader to check against his or her own clinical experience: 1) more than 70% of even seriously impaired alcoholics improved after treatment, 2) the fact of treatment was more important than the specific type of treatment, provided the treatment was given in sufficient amounts, and 3) the majority of improved clients were drinking moderate amounts of alcohol at levels far below what could be described as alcoholic drinking.

Although the third conclusion was the red flag that inflamed the alcoholism establishment and, especially, recovered alcoholics whose very lives depended on abstinence, clinicians who treat large numbers of alcoholics were relatively unmoved. They were only too well aware of how many patients try to prove wrong therapists who prescribe abstinence by "controlling" their drinking. This may go on for many months without any apparent adverse consequences, but the tenuous sobriety thus maintained is scarcely serene when there is a need to "control" one's drinking, a condition almost pathognomonically different from the social drinking of nonalcoholics.

The longest follow-up of controlled drinking therapy (2 to 55 months) was that of Ewing and Rouse (1), excellent clinicians who were directly involved in the treatment process. Ewing and Rouse found that controlled drinking looked promising in the first 12–18 months but in the longer run was "a universal failure."

One may perhaps forgive sociologists and medical laymen for misunderstanding the degree of immediacy implied in the language of the familiar Alcoholics Anonymous dictum that "an alcoholic is one drink away from a drunk." Of the alcoholic patients who choose to return to some degree of controlled drinking an unknown number may well be successful, just as there are diagnosed cancer cases in remission in the literature. Most physicians with a large alcoholism practice would agree that the alcoholic who can return to drinking behavior without relapsing into dependence is rare. Since we are unable to preselect such individuals, it can scarcely be called responsible practice to recommend a treatment with so little chance of success.

To set the record straight, the authors of this report do not advocate that alcoholics try moderate drinking after treatment. On the contrary, they expressly warn that "alcoholics who have repeatedly failed to moderate their drinking, who have irreversible physical complications due to alcohol, should not drink at all" (p. 295). They also clearly state that their conclusions have no relevance for future policy without further research.

It seems strange that although the authors include comment on much of the criticism of their work, they did not include a memorandum from the Deputy Director of the Division of Special Treatment and Rehabilitation Programs of the National Institute on Alcohol and Alcohol Abuse dated June 18, 1976. This memorandum sheds considerable light on the report's shortcomings. It states that the subjects in the study comprised a more diverse "problem drinking" and less "definitely alcoholic" population than the Rand researchers suggest. It also questions the acceptance of the consumption of 3 oz. of ethanol as normal drinking. The document concludes,

It is very likely that a substantial number of clients in the

samples are misclassified as definite alcoholics when, in fact, many are suffering from a variety of problems related to alcohol abuse but without the severe impairment or physical dependence which characterizes the more commonly held definitions of the definitely alcoholic. . . . Armor et al. have not established that the physically dependent alcoholic person can become a normal drinker, in large part because the assumptions and definitions adopted for the study are unjustified, appear to be arbitrary or self-serving and therefore are unconvincing.

Baltimore, Md.

search Advances in Alcohol and Drug Problems, Vol. 4, *ed-d by Yedy Israel, Frederick B. Glaser, Harold Kalant, bert E. Popham, Wolfgang Schmidt, and Reginald G. iart. New York, N.Y., Plenum Press, 1978, 485 pp., 9.50.*

This book contains an interesting mixture of critical views current research advances regarding various aspects of ohol and drug problems. For example, there are chapters aling with the biological significance of endogenous opiod ptides and the opiate receptors, brain reinforcement cens and the psychoactive drugs, animal studies of alcohol thdrawal reactions, and the role of acetaldehyde in the meolism and reactions of alcohol.

Clinical and social concerns are dealt with in such chaps as a detailed history of the tavern through the ages, pant characteristics as predictors of treatment outcome, the el of consumption and the social consequences of drinkg, alcohol use among North American Blacks, the etiolcal relationship between drug use and criminality, the reults of decriminalization of public drunkenness, and the atment of cigarette dependence.

All of these subjects are discussed in a highly technical d scientific manner that requires concentrated but interting reading. I was amazed that a book could be published quickly with such up-to-date research material and with ch an extensive bibliography of references to the current erature. The editors are to be congratulated for producing professional and scholarly treatise that must have entailed great deal of effort.

FREDERICK LEMERE, M.D.
Seattle, Wash.

andbook of Adolescence: Psychopathology, Antisocial Develment, Psychotherapy, *by Carl P. Malmquist, M.D. New rk, N.Y., Jason Aronson, 1978, 879 pp., $30.00*

Anyone who ventures to capture a whole stage of man in a gle volume must make choices. Malmquist has chosen beviors that bring adolescents to court, and his book is most teresting and valuable in this respect. It also covers a great ny other areas, but in nonforensic matters, particularly in clinical terms, the book is less detailed. Really not a handbook but a series of essays reflecting the author's interests and best read in their entirety, these 879 pages with more than 1,100 references are imposing.

The author's discussions of forensic issues are particularly interesting with respect to adolescent sexual behavior, in which are incorporated the historical background, a broad perspective on sexual crimes and deviations, and a sophisticated view of unsolved problems at the interface of society and therapist. The author's treatment of such issues as censorship and psychopathy is thoughtful and informed, and his heartfelt chapter titled "The Juvenile and the System of Justice" clearly reflects long exposure to the vicissitudes of courts and the inadequacies of treatment and punishment alike for this population.

The clinician may at first be intrigued by the author's decision to include all nosological conditions from neuroses through character disorders to psychoses under the rubric of "antisocial behavior." Inevitably those in forensic work will encounter all varieties of adolescent pathology. However, such an approach may make it difficult to identify patients encountered in clinical practice. Although the title page promises a discussion of psychopathology, antisocial development, and psychotherapy, only the second of these three is treated in depth. Illnesses such as manic depression and symptom complexes such as school phobia are scarcely mentioned, anorexia nervosa rates only a line or two in passing, and even schizophrenia receives relatively brief discussion. Medication is not covered, medical illnesses and their emotional consequences get short shrift, and the discussion of the biological area is somewhat dated throughout the book.

Despite such clinical shortcomings, this is a substantial book. Some of the discussion is extremely complete, going well beyond the adolescent age group; if other aspects are weak, this may reflect the herculean labor such an undertaking must have presented a single author. An introduction might have clarified his expectations for this work, and the book would have benefited from more thorough editing, proofreading, and indexing to render its real contributions in the area of adolescent forensic psychiatry easier to reach.

CHRISTOPHER H. HODGMAN, M.D.
Rochester, N.Y.

Motivation: Theories and Principles, *by Robert C. Beck. Englewood Cliffs, N.J., Prentice-Hall, 1978, 459 pp., $12.95.*

Not all efforts to systematize what is known about behavior and its determinants—i.e., the field of psychology—make great use of the concept of motivation. Indeed, B.F. Skinner's classic, *The Behavior of Organisms* (1), which is probably the single most influential treatise on psychology of this century, contains no chapter on motivation; the word does not appear in the index of that volume. Others have found motivation to be a useful integrating concept around which much psychological theory and many psychological principles can be organized. The present volume does this quite well.

This book does not deal systematically with abnormal behavior or topics in clinical psychology and psychiatry. Nor does the author deal with psychodynamic theories or concepts. Rather, the book offers an introduction to basic psychology as a natural science derived mainly from experimental work in animal and human laboratories. Using the core

notion of motivation as a starting point, the author offers succinct, historical introductions and resumés of current experimentally based thinking on a number of related topics. These include the concept of drive, activation and arousal, reinforcement theory, aspects of fear, avoidance and escape learning, experimental aspects of anxiety, conflict and aggression, and other topics. Particularly strong is the chapter on physiology of consummatory behaviors. For example, the section on hunger nicely summarizes the state of knowledge on the role of hypothalamic factors in eating, other brain areas, sensorimotor and motivational deficits, and the more peripheral physiological factors such as stomach distension, osmotic balance, and intestinal volume. The literature on specific hungers is also summarized.

Because of the breadth of this volume, the author deals with no topic in great depth and does not include the most recent experimental findings. However, the volume will be very useful to the clinician or investigator who wants an accurate, comprehensive, understandable, and brief review of one or another aspect of behavior viewed from a motivational perspective.

JOHN PAUL BRADY, M.D.
Philadelphia, Pa.

Annual Review of the Schizophrenic Syndrome 1976–1977, *edited by Robert Cancro, M.D. New York, N.Y., Brunner/Mazel, 1978, 636 pp., $27.50.*

This impressive and scholarly collection of world literature in the field of schizophrenia research is a valuable reference volume. The editor's encyclopedic knowledge is reflected in his concise and helpful comments about papers that were not included in the 31 chapters. There is a strong tendency toward highly abstract and theoretical papers. This fits with the relative paucity of direct clinical material and with the book's role as a reference work as opposed to a textbook.

Strong emphasis is placed on genetic and family studies of schizophrenia. An outstanding chapter is that of Julian Leff on "Schizophrenia and Sensitivity to the Family Environment." Leff clearly demonstrates the importance of expressed emotion, by which he means criticism and hostility by a parent or spouse at the time of admission of a schizophrenic patient. This variable was found to be significant in terms of relapse and rehospitalization within one year. A standardized test that would allow clinicians to reliably measure this variable would be helpful in formulating post-discharge plans. Another related variable was the patient's spending 35 hours a week or more in direct face-to-face contact with a critical relative. This factor also increased the relapse rate. The findings suggest that under certain circumstances schizophrenic "withdrawal" may help the patient avoid stressful interaction within the family.

Perhaps the finest chapter is that by Robert Heath on "Brain Function and Behavior" reprinted from the *Journal of Nervous and Mental Disease*. Heath gives a clear, well-reasoned overview of the research program in the Department of Psychiatry and Neurology of Tulane University since 1949. The research has focused on developing treatment for patients resistant to commonly used therapies. work has often been controversial, but Heath clearly plains the need for human experimentation (such as electrode implants, done stereotactically) as the logical tension of animal brain research done in the Tulane labo ries. He has demonstrated that the septal region "has ur ingly shown aberrant electrical activity, in the form of sp and slow waves, during psychotic episodes, regardles cause" (p. 197). Heath has made important advances in c lating brain activity with specific emotions. His findings "do not coincide with conventional textbook presentati (p. 197), probably indicating that he continues to work or frontiers of scientific knowledge. He provides an eleg though complex, neuroanatomical summary in his figur (p. 214), a diagram of a monkey brain against the backgrc of stereotaxic coordinates. This chapter is an essential re of how Heath and his colleagues have advanced our un standing of the anatomical-functional substrate for emoti

CHARLES A. LEVIE, M.I
Springfield, Ir

Drugs of Abuse: Handbook of Psychopharmacology, Vol. *edited by Leslie L. Iversen, Susan D. Iversen, and Solor H. Snyder. New York, N.Y., Plenum Press, 1978, 412 p $32.50.*

Although this is a review of volume 12 of the *Handboo Psychopharmacology,* it is impossible to do justice to volume without mentioning the scope of the *Handbook* whole. Other volumes have dealt with classes of drugs v significant abuse potential. The title of volume 12 is r leading because one cannot gain a comprehensive overv of abuse by reference to this volume alone. The 14 volu of the *Handbook* have attempted to cover basic neuropl macology (volumes 1–6), behavioral pharmacology in mals (volumes 7–9), and human psychopharmacology (v umes 10–14). Each volume presents an in-depth review given topic by authorities in the field. The *Handbook* s ceeds very well in providing an encyclopedic overview what is known about psychopharmacology.

This volume consists of 7 chapters, each of which i comprehensive review of a given area. These chapters not easy reading for the generalist; most of them are tecl cal, sophisticated, and brief. They do not offer easy planations of complex issues. They presuppose a level technical understanding that most practitioners may have. This is a reference book, a collection of reviews scientific data concerning human psychopharmacology necessarily clinically oriented. For the student and pro sional who wants an overview of the current state of kno edge, the content of this book is well worth the effort of re ing it.

Chapter one, "Drug Self Administration: An Analysis the Reinforcing Effects of Drugs," summarizes the major imal research on drug self-administration. It is a clear straightforward exposition of the philosophy, techniqu and results of such animal research. Unfortunately no tempt is made to present, even speculatively, the impli tions of this research for human behavior, nor are any ref ences made to comparable research in humans.

Chapters two and three, "Analgesics and Their Anta nists: Structure-Activity Relationships" and "Opiates: H man Psychopharmacology," complement each other. T well written discussion of structure-activity relationsh

esents an extraordinary amount of information and is a od guide for anyone who wants to learn more about this pic. Social historical data are interwoven with the latest ormation concerning structure-activity relationships. The thor of this chapter, Jacobson, acknowledges that "unfor- nately, we are without a viable theory that can quan- atively relate molecular structure to biological activity for r multitude of analgesics." Mansky's overview of opiates ings together an impressive amount of information in a adable form. There are many good clinical observations oughout the chapter, and anyone working with narcotic dicts can benefit from this review.

There is no companion chapter on human psycho- armacology for chapter four, "Sedative-Hypnotics: Ani- al Pharmacology," and this is a weakness of this volume. apter five, "Alcohol and Human Behavior" is one of the tter overviews of this topic. It is scholarly, well-written, d packed with information. The authors, Mello and Men- lson, state that "the effects of alcohol on human behavior e diverse and complex and rarely in accord with traditional liefs. . . . Alcohol abuse often results in a distortion of ny of the simplest alcohol-related pleasures. The once sitive effects of alcohol are often transformed into their tithesis."

Finally, chapters six and seven deal with "Cannabis: ructure-Activity Relationships" and "Marihuana: Human fects." There may be a little sophistry involved in calling e drug cannabis when one is discussing structure-activity lationships and marijuana for human effects, but these apters present good overviews of the subject and are valu- le for anyone interested in the subject matter. A system of oss-referencing to other chapters within the *Handbook*, nilar to that done in the *Comprehensive Textbook of Psy- iatry* (1), would have enhanced the value of this series as a hole.

Sacramento, Calif.

ie Psychology of the Self: A Casebook, *written with the col- boration of Heinz Kohut, M.D.; edited by Arnold Gold- rg, M.D. New York, N.Y., International Universities ess, 1978, 456 pp., $20.00.*

This book by a group of bold and sensitive clinicians is a llection of six cases. The analysts expose their discomfort, rors, uncertainties, and hesitations as they struggled to ap- y Kohut's formulations to their analytic work with narcis- stic patients. They take Kohut's metapsychological termi- logy and give it context and depth with extensive clinical ta. Their work gives a clear picture of Kohut's under- anding of the dynamics and treatment of narcissism; it also ings into focus many of the questions his formulations ise.

A key aspect of Kohut's theory is the concept of a sepa- te line of development for narcissism with its own stage- lated tasks and human environmental needs (1, 2). Kohut arifies the child's normal exhibitionism and grandiosity and s need for his parents to accept these qualities as they mir- ror his realistic attributes and assets. He suggests that parental "mirroring" supports the child's capacity to develop a coherent sense of self. Phase-appropriate tolerable frustration of mirroring needs allows the child's grandiosity and exhibitionism to be transformed into mature narcissism, ambition, and internally regulated self-esteem. A second crucial aspect of the child's "bipolar self" is his need to lean on idealized parents who can initially accept his idealization. Gradual phase-appropriate disenchantment with idealized parents contributes to the child's development of internalized ideals.

Failure in this careful choreography contributes to defects in the self, which are manifest by unmodulated grandiosity or exhibitionism, a tendency to fragmentation or overstimulation, empty depressions, narcissistic relationships with others, and continuing dependency on others to support fragile self-esteem.

Through a study of the transferences in these six cases, the analysts present a picture of the nature of parental failure in supporting the child's narcissistic development. The parents are seen as preoccupied with themselves, unaccepting or unavailable, devaluing of the child or of themselves, intrusive, exhibitionistic, and unempathic. As the analysts attempted to understand their patients, they saw how classical analytic interventions themselves became the sources in the transference for the repetitive trauma the patients feared the most. Oedipal interpretations were heard by these patients as echoes of their parents' attempts to lay their own meanings on the child. Often, the patient's angry and desperate response to these interpretations took the form of, "All you do is interpret, you won't take me seriously. You don't believe me." The patients' extraordinary sensitivity, vulnerability, and susceptibility to humiliation and fragmentation required a shift in the analysts' interpretive focus.

With Kohut's new perspective, these analysts were able to interpret their patients' responses as repetitions of early experiences of nonacceptance and intrusion. The analysts' acceptance and interpretation of their patients' need for mirroring responses and of their need for an idealization of the analyst evoked confirming early memories and a developing acceptance and perspective in the patients of their unintegrated narcissistic needs. In many of the cases the clinical material demonstrates how the analysts' empathic failures were used by the patients to recognize their earlier trauma and work it through in a new context so that they could internalize a more stable and coherent sense of themselves. This process resulted in significant improvement in the patients' creative capacities, ambitions, and sense of independence.

Despite the richness and openness of the case material, important questions about these clinicians' conceptualizations of the analytic experience remain. In many of the cases, interpretation alone appeared to be sufficient. However, in others direct gratification (e.g., admiration, loaning money) was used by the analysts without adequate clarification of how the intervention was understood. It is important to know how an analyst reaches the determination that a patient cannot stand the deprivation of an interpretation without being disruptively humiliated. In addition, the authors' focus on narcissistic issues leaves the reader with a somewhat monochromatic view of these patients. Many alternative formulations are raised only to be too rapidly dismissed; one is left wondering about alternative or additional perspectives from which to view the material.

Finally, it remains unclear how a mutually agreed on termination can be reached when the patient does not relate to the analyst as a whole object. For several of these cases,

although many narcissistic issues had been worked through, much seemed to remain untouched at termination. It would be helpful to know how these analysts determined when to relinquish their attempts to move beyond the narcissistic transference with the patient.

This is an evocative book. If many issues remain unclear it is because the concepts are still in their formative stages. The contributors of these case reports invite us to struggle with these issues along with them. They have given us the basic data to help us examine their thinking.

The Therapeutic Interaction: A Synthesis, *by Robert Langs, M.D. New York, N.Y., Jason Aronson, 1977, 195 pp., $50.00.*

Robert Langs belongs to a group of psychoanalysts who have stressed what I would characterize as the hyperalert, hypertechnical, almost suspicious approach to the psychoanalytic process. Since the early 1970s Langs' productivity has been staggering, including five lengthy personally authored volumes as well as an impressive list of edited books on clinical psychoanalysis and its application. However, it is difficult to assess the impact of these works on the profession at large, particularly because they tend to fall between various groups of clinicians. Langs' obsessional concern with maintaining the psychoanalytic framework and detailing the interaction between psychoanalyst and patient is certainly beyond the concern of most psychiatric psychotherapists. Classically trained psychoanalysts tend to turn to more established texts on the issues of psychoanalytic technique.

In my view, Langs' approach to psychoanalysis and psychoanalytic psychotherapy is far from comfortable or satisfactory. If critics of psychoanalysis have tended to be overly harsh in their criticism or dismissive in their judgments of psychoanalysis, psychoanalysts like Langs have erred in the direction of overvaluing the psychoanalyst's power by attributing to psychoanalysis a monopoly on curative factors for emotionally based illnesses while insisting on flawless technique as essential. Langs represents the extreme end of this spectrum of psychoanalysts who attribute excessive importance to technique.

Even more significant than Langs' willingness to dismiss other approaches to psychotherapy and psychoanalysis is the effect of his "purist" approach to psychoanalytic technique. At the end of this brief volume he states, "Looking back over this synthesis, I am reminded again of the virtual impossibility of the analyst to maintain constant mastery over the incredibly complex relationship between himself and the analysand." This attempt to maintain complete and constant mastery or, more precisely, control over all aspects of the analytic relationship is what seems to me to be a major limitation of the author's approach. In his hands psychoanalysis becomes an endeavor of such technical difficulty and virtuosity as to defy practice by reasonably intelligent, well-educated psychoanalysts. Pitfalls are everywhere. The analyst is continually in danger of being misled or seduced by the patient, and the patient must beware of the analyst's countertransference. The analyst must scrutinize every aspect of his or her interaction with the patient to what appears to me to be a crippling extent. This constant stress of the need for purity and vigilance gives much of this volume the feel of a moral tract.

In his closing paragraphs Langs anticipates criticism from other analysts because of his tendency to stress interaction aspects of the analytic process. However, he does not seem aware of the possibility that criticism of his ideas might come from another source, namely, the degree of technical rigidity he advocates. Langs has also felt it important to characterize the interactional aspect of the psychoanalytic process in terms of projective identification and introjective identification. He borrows these terms freely from the Kleinian school of psychoanalysis while maintaining that his is a classical stance on the technique of psychoanalysis. These concepts, which seem to me to be questionable at best, are then used further in the service of technical rigidification and suspiciousness of the patient and the analyst.

I think there is considerable irony in the fact that although Langs writes extensively about the therapeutic alliance, his adherence to the concept of projective identification and introjective identification is a major barrier to anything approaching basic trust in the psychotherapeutic relationship. This then seems to me to be a book greatly marred by psychoanalytic chauvinism. It is unlikely to win friends for psychoanalysis or to help individuals who, while not practicing psychoanalysis proper, use findings from psychoanalysis and modified psychoanalytic techniques in conducting psychotherapy. Those searching for a nonchauvinistic, helpful clarification of how to be both psychoanalytically oriented and human will not find it in this volume. I think, in fact, that it would have a negative effect on an individual's clinical flexibility.

HENRY J. FRIEDMAN, M.D.
Boston, Mass.

C.G. Jung: The Haunted Prophet, *by Paul J. Stern. New York, N.Y., Delta (Dell Publishing Co.), 1977, 262 pp., $3. (paper).*

Thanks to three-quarters of a century of research into the depths of the psyche, we are very familiar with the phenomenon of transference, the putting onto another person of our own psychic attitudes and contents of which we are unaware. Chief among such projections are those which originate in our own earliest past that have long been forgotten and repressed into the unconscious—feelings about parents, siblings, and other significant members of our early environment. We know well that our transference of past unresolved emotions into significant present-day relationships can be strongly tinged with negative or positive flavor. No one is immune to this natural process of projection. The only way this autonomous process can be altered is through the intervention of conscious understanding and the assimilation of the unconscious contents in transference.

Analysts themselves fall victim to transference, frequently in a positive way to their psychological mentor or negatively against a founder of an opposing school of depth psychology. The hallmarks of unresolved transference clearly announce that projections are taking place. We feel especially agitated about the person onto whom we are projecting—that person has gotten under our skin and we strongly overreact. We feel

mpulsively gripped by our reactions and neither measure
modify the tone of adoration, if the transference is posi-
, or of captious, even vitriolic attack if the transference is
ative. We are caught in unconscious identification with
person onto whom the transference has been made. We
not extricate ourselves and give the impression of thrash-
about in an irrational manner to get free.

aul Stern's book on Jung bears all the marks of negative
sference. His pages abound in sarcastic remarks and be-
ing commentary. His authoritative tone and frequent use
what look like precise details, in some cases with quota-
s, are all the more remarkable because the book has no
tnote data whatsoever. The reader is left wondering how
ch of what Stern asserts as fact stems from his endow-
nt of his subject with his own negative reactions.

he reader may be even more puzzled about the source of
author's disproportionately intense reactions to Jung and
y he even bothered to write this screed. The book is not
ful as an introduction to Jung's thought or as a critical
luation of the analytical procedures with which it is asso-
ed. There may be some value in the work for those
ght in too passionately positive a transference to Jung
his ideas. For them, Stern's too passionately negative
ctions might suggest a better balance.

ANN BELFORD ULANOV, PH.D.
New York, N.Y.

**ld Abuser: A Study of Child Abusers in Self-Help Group
rapy,** *by Marilyn C. Collins, Ph.D. Littleton, Mass., 3 Publishing Co., 1978, 124 pp., $12.50.*

ommiseration can offer comfort to group participants. A
pite from suffering and a source of strength, comfort de-
s from joining a body greater than the individual self. The
ole becomes more than the sum of its parts. This principle
been institutionalized in various self-help movements
r the past several decades. Perhaps the best known is
oholics Anonymous. We can assume that Parents Anon-
ous borrowed their name and, perhaps, their ideology
n Alcoholics Anonymous.

his book offers a description of the Parents Anonymous
vement as reported by a social scientist who served as a
nsor for a group of mothers who had abused their chil-
n. The author draws on her experience as a participant-
erver to assess the causes and suggest a solution for the
blem of child abuse. Her technique of quoting interviews
1 abusing mothers lends a refreshing vitality to data that
ht otherwise be buried by the obscure phraseology that
vails when the text turns from clinical material to a dis-
sion of ideas.

he author characterizes the therapeutic consequences of
icipation in Parents Anonymous as following six stages
he "moral career of a child abuser." Starting from stage
, "being different and feeling guilty," the participants
n alternative behavior patterns to physically abusing
r children. The telephone is heavily relied on as a means
ontacting group members whenever the impulse to abuse
ild arises. This technique, used extensively in Alcoholics
onymous, appears to work well for members of Parents
onymous as well.

he author states that the modification of abusive behav-
depends on "coming out" as a child abuser. A public
laration among a group of peers constitutes an essential
fessional technique as a step toward attaining stage six,
oral self-acceptance and becoming a recruiter."

The ultimate therapeutic goal of the Parents Anonymous program is the attainment of a "career of affiliation." This is defined by the author as being "an experienced child abuser, skilled as a lay therapist." The author faults the efforts of other workers for having failed to offer this form of solution:

> Few "rehabilitative" programs for child abusers at any level, whether part of the private or public sector, offer the opportunity to their participants to graduate from the stigma that defined their need of rehabilitation to begin with. The major flaw in these programs is their lack of an affiliation clause. (p. 108)

In her approach to this complex problem, the author relies on the writings of Becker, Goffman, and other social scientists, several of whom are not listed in the bibliography although their work is cited in the text. The psychiatrist reader of this book will find scant reference to individual dynamics, although "lowered self-esteem" is cited as a cause of abusive behavior. Although the author emphasizes that this problem is not limited to the lower socioeconomic classes, she makes no effort to search for an explanation that might transcend the limitations of social theory.

The book raises several points about which there could be extended discussion. The substitution of one activity for another is a well-recognized technique for modifying behavior. It has been used to alter alcoholism, drug addiction, phobias, and sexual inhibitions. Substituting disulfiram, methadone, inspirational phrases, and erotic imagery can be employed to counter temporarily the threat posed by unmastered appetites. However, substitution of actions, no matter how effective an adjunct in changing the social dimension of behavior, should not be equated with a transformation of motivation.

The goal of a "career of affiliation" presents another questionable item. The status of *ex,* whether drunk, con, or child abuser, is not in itself a qualification to treat others afflicted with the condition. Child abuse is a discrete clinical syndrome manifesting a pervasive, deep, and pressing problem, the mastery of aggression. The tendency to formulate simple solutions for this complex issue, although understandable, is fraught with hazards. Simple solutions suggest that the problem is simple. It is not. Child abuse draws on issues of human pathology from the deepest levels of individual development and social adaptation. An understanding of the phenomenon is not likely to be granted those who choose to pursue a simplistic approach.

RICHARD GALDSTON, M.D.
Boston, Mass.

Society, Stress, and Disease, Vol. 3: The Productive and Reproductive Age—Male/Female Roles and Relationships, *edited by Lennart Levi, M.D. New York, N.Y., Oxford University Press, 1978, 279 pp., $41.00.*

This volume is one of an increasing wave of books growing from the conviction that if one convenes a symposium of well-known names in a given field the presentations should be published. This volume is a convincing counterargument.

Within its modest page length it contains 37 chapters by nearly as many different authors as well as a synopsis of the general discussion. There are a few exceptional chapters. Two by Henry and associates correlate the breakdown of normal male/female role differentiation in experimental mu-

rine populations with total disruption of reproductive patterns, maternal care, offspring survival, and social control of aggression ensuring colony survival. They further document the correlation of such stress with physiological disturbance and physical pathology and discuss the data suggesting that these findings may extrapolate to humans. Liljestrom offers a sensible discussion of the different stresses generated in role-differentiated versus role-shared young nuclear families, indicating that the trade-off of stresses for both parents and children does not strongly favor either pattern. Gebhard presents previously unpublished data from the Kinsey research on subjectively perceived sources of marital stress.

Unfortunately, these presentations represent exceptions. Most of the chapters are so brief that they permit generalizations and truisms more appropriate to high school texts or provide sociological documentation of the obvious. With few exceptions the format does not encourage the presentation of new or detailed data or carefully reasoned and documented broad conclusions. Mead's three pages of generalizations about cross-cultural determinants of male/female roles, followed by five pages of tiny print references that are not noted in the text is an unbecoming exercise in condescension.

The book does have a predominant theme—the plea for psychosocial equality for women—but here too there are more sorrows than joys in the presentation despite the philosophical acceptability of that goal. The advocacy of sociopolitical goals in a scientific forum can lead to carelessness in the supports one calls on. Blatantly undocumented statements such as, "Most female neuroses are a result of societal demands and discrimination rather than the supposed mental illness of the individual," are adduced as scientific support. There is often a fuzzy indistinction between "equal" and "identical." State-supported social engineering to produce androgeny in young children is presented as an unquestioned good, with the implication that it is scientifically supported but without attention even to the cautionary data cited in this volume.

It is difficult to identify an audience for whom this book could be recommended. It is too uneven and confusing to benefit the unsophisticated student and offers too little new data or sound and careful scholarship for the knowledgeable professional in the field of male/female roles and traits.

WARREN J. GADPAILLE, M.D.
Denver, Colo.

Notizen zu Martin Heidegger, *by Karl Jaspers; edited by Hans Saner. Munich, Germany, R. Piper & Co., 1978, 342 pp., 29.30 deutsch marks.*

Karl Jaspers wrote notes on Martin Heidegger for more than 30 years, from 1928 to 1964. These were written with the intention of producing a comprehensive critique of Heidegger, but Jaspers, who died in 1969, did not complete the work, nor did he edit these notes; these have been done by one of his assistants.

Jaspers and Heidegger first met in 1920. Both hoped that a friendship might develop because they felt united in the desire to combat the traditional formalistic philosophy taught in German universities at that time. In the case of Jaspers, this was related to the fact that he had no formal training in philosophy and had entered this field through the "back door" of medicine, psychiatry, and psychology. His *General Psychopathology* had appeared in 1913.

A hesitant and somewhat ambivalent friendship seer have existed in fact until 1933. During this time their philosophical works were published: Heidegger's *Sein Zeit* (1927) and Jaspers' three-volume *Philosophie* (1 The relationship was interrupted by the effects of poli events, which were quite different for the two. Heide pronounced himself publicly to be a convinced nationa cialist (Jaspers says Heidegger was no opportunist) and came the first national socialist rector of his university (F burg). After a year, apparently, Heidegger was discarde the party (Jaspers states Heidegger was entirely naïve pc cally as well as in all aspects of practical life such as finar and in science and medicine).

Jaspers, on the other hand, although he initially had clear ideas about the new government, quickly got into flict with it. From 1937 on he was not allowed to teacl publish; during the war both he and his Jewish wife wer constant danger of being arrested. After 1945, Jaspers fered to reconcile with Heidegger if he would make a pu statement acknowledging his earlier error; this was not fo coming, and Heidegger later stated publicly that it ne would. This resulted in the abandoning of further attempt reconciliation between the two philosophers.

The notes largely represent Jaspers' attempt to underst the reasons for this failure. He found them in both Heic ger's philosophy and his personality. We learn in the edit introduction that, as might be expected, the reasons ar part to be sought on Jaspers' side, who was quite sensitiv criticisms by his colleague. Jaspers continued to be ambi lent about Heidegger, but his negative opinions tendec become stronger as the years passed by. The principal ferences between them, as he saw it, were in the degre personal involvement in philosophy. He saw Heidegge attempting to construct an objective philosophical edific if it were a branch of science and independent of the one had constructed it. Jaspers considered this a fatal error f philosopher: "This is akin to founding a religion." viewed Heidegger as a sort of magician with a very powe and beautiful writing style that could become a domir force to the detriment of the subject matter. Heidegger quired a much larger following than Jaspers, and Jas thought that he had strong authoritarian inclinations. Her of course the suspected link with the political involvem

The fact remains that Jaspers considered Heidegger only person of comparable rank in his field. At one poin even considered that Heidegger may have had more im tant things to say: "But this only one was my polite ene The powers we served were incompatible. Soon it appe that we could not even talk to each other." Still, he no when someone attacked Heidegger, he found himself fending him, "not because I agree with him but because type of critique does not touch the points which seem to to be the philosophically essential ones."

H.F. MÜLLER, M.D
Montreal, Que., Canad

Coding the Therapeutic Process: Emblems of Encounter Manual for Counsellors and Therapists, *by Murray Cox. N York, N.Y., Pergamon Press, 1978, 77 pp., $7.50 (paper*

Structuring the Therapeutic Process: Compromise Chaos—the Therapist's Response to the Individual and Group, *by Murray Cox. New York, N.Y., Pergamon Pr 1978, 292 pp., $10.00 (paper).*

Dr. Cox has written two outstanding books for psychotherapists in all disciplines. He writes as an individual and group therapist in private practice and as a psychotherapist at Broadmoor, a hospital for those who "require treatment under conditions of special security on account of their dangerous, violent, or criminal propensity." Thus, what Dr. Cox says in these books is derived from an unusually diverse experience.

Structuring the Therapeutic Process is a literate, wise, and witty book. It is also eclectic. Dr. Cox has gathered a rich harvest from many sources. He is less concerned about schools of thought than he is about what he feels is the "core dynamic of psychotherapy," i.e., emotional disclosure. Facilitation of disclosure occurs, no matter what therapeutic orientation is used, when there is congruence of perspective, when the therapist can view the world from within the patient. The patient becomes more trusting as the therapist comes closer to risking, in Dr. Cox's words, "his own ontological security."

There is authenticity and honesty in Dr. Cox's message. Therapists who are already aware of the fact that they reach therapeutic turning points when they risk their own vulnerability will be supported by the framework he provides. Other therapists will be encouraged to try to use their own emotional responsivity for intervention.

The position presented does not support casual statements by the therapist. It is the patient who associates, not the therapist. Dr. Cox presents a structure for filtering out what is said through a therapeutic vigilance that comes from receptivity to the patient's needs, talents, and, occasionally, desperation. The therapist primarily wants to help the patient; what he or she learns about himself or herself stands apart from and is always secondary to that goal.

The author does not convey a sense of working against tide and wind; there is a unique pleasure in such encounters. He writes, for example, of the necessity to have patients express those moments which give pleasure as much as those which give pain. He points to the possibility that some therapists are threatened by a patient's joy and thus may tend to never elicit disclosures about it. He addresses in depth the problems of transference and countertransference as he describes what is for him the essential characteristic of the therapist—emotional accessibility and tolerance for any and all of the patient's disclosures. There is the difficult and paradoxical task of mastering affective neutrality while maintaining accessibility to such feelings.

Coding the Therapeutic Process, the companion volume, is focused on a visual display system (VDS), a device for notation applicable to encounters with patients. A VDS can be a helpful guideline and marker when a therapist attempts to grasp and retain the dynamic content of patient interactions over time. This book also has many of Dr. Cox's insights into the process of psychotherapy. Perhaps it would be improved by an extended version presenting further examples. The notation used has great promise as an extremely helpful conceptual tool for the group therapist in clinical work and research. Therapists who have been concerned with problems of notation will benefit from the ideas contained in this volume.

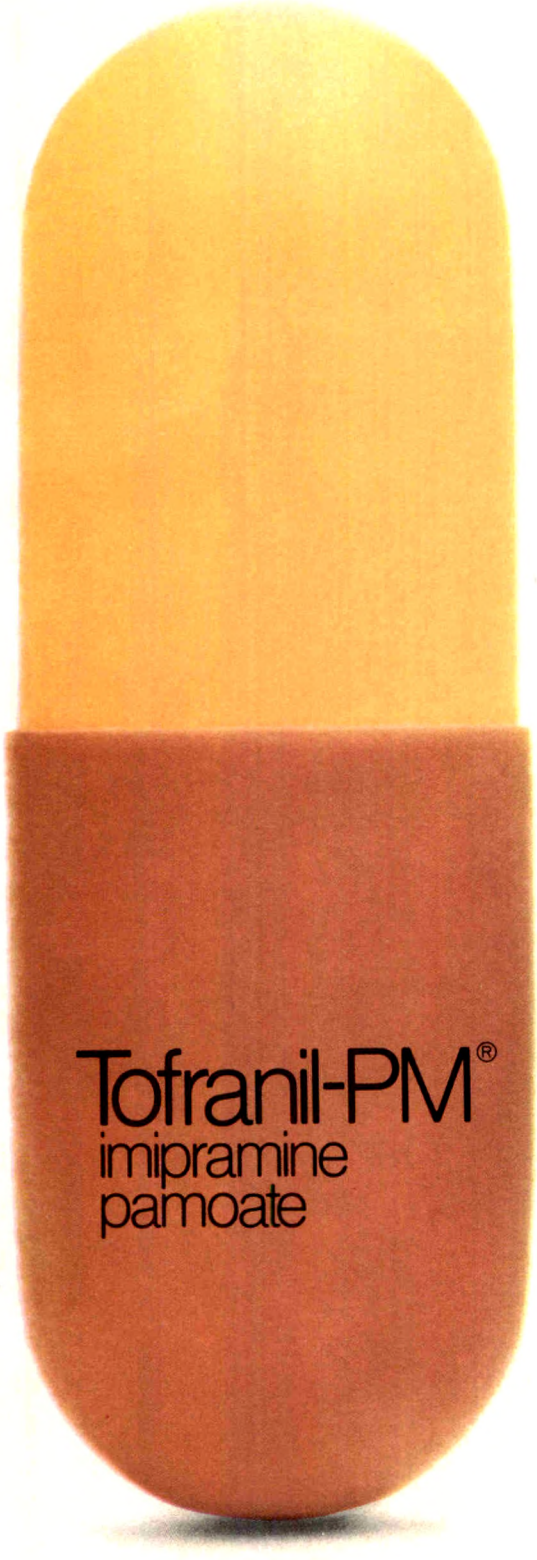
OFFICIAL ACTIONS

Position Statement on Abortion

This statement was approved by the Assembly of District Branches at its October 15, 1978, meeting and by the Board of Trustees at its December 10, 1977, meeting. This final draft was drawn up by a subcommittee[1] appointed by the Reference Committee to collate an Area I Action Paper and information provided by the Committee on Women, the Council on National Affairs, the Council on Children, Adolescents, and Their Families, and the American Academy of Child Psychiatry.



THE EMOTIONAL CONSEQUENCES of unwanted pregnancy on parents and their offspring may lead to long-standing life distress and disability, and the children of unwanted pregnancies are at high risk for abuse, neglect, mental illness, and deprivation of the quality of life. Pregnancy that results from undue coercion, rape, or incest creates even greater potential distress or disability in the child and the parents. The adolescent most vulnerable to early pregnancy is the product of adverse sociocultural conditions involving poverty, discrimination, and family disorganization, and statistics indicate that the resulting pregnancy is laden with medical complications which threaten the well-being of mother and fetus. The delivery that ensues from teenage pregnancy prone to prematurity and major threats to the health mother and child, and the resulting newborns have a high percentage of birth defects, developmental difficulties, and poorer life and health expectancy than the average for o society. Such children are often not released for adoptic and thus get caught in the web of foster care and welfa systems, possibly entering lifetimes of dependency and cos ly social interventions. The tendency of this pattern to pa from generation to generation is very marked and th serves to perpetuate a cycle of social and educational failur mental and physical illness, and serious delinquency.

Because of these considerations, and in the interest public welfare, the American Psychiatric Association 1) o poses all constitutional amendments, legislation, and regul tions curtailing family planning and abortion services to a segment of the population; 2) reaffirms its position that abc tion is a medical procedure in which physicians should r spect the patient's right to freedom of choice—psychiatris may be called on as consultants to the patient or physician those cases in which the patient or physician requests su consultation to expand mutual appreciation of motivati and consequences; and 3) affirms that the freedom to act interrupt pregnancy must be considered a mental health i perative with major social and mental health implications

[1]The subcommittee included Edward H. Futterman, M.D., chairperson of the Council on Children, Adolescents, and Their Families; James M. Stubblebine, M.D., chairperson of the Council on Mental Health Services; Harold M. Visotsky, M.D., chairperson of the Council on National Affairs (1975–1978); Jeanne Spurlock, M.D., staff liaison; and Jay Cutler, staff legal counsel.

ıany patients

HE RIGHT ANTIDEPRESSANT

No tricyclic antidepressant works more effectively to brighten the mood, relieve sleep disturbances, and ameliorate mild anxiety.[1,2] And none appears to be better balanced[3] in terms of the biogenic amine theory of depression, which relates depression to functional deficiencies of the catecholamines.

For Tofranil-PM is almost equally effective in inhibiting the postsynaptic uptake of both serotonin and norepinephrine, the two neurotransmitters most often implicated in depression, while other tricyclic antidepressants tested are heavily skewed towards one or the other.*

*Nortriptyline, a chemical derivative of amitriptyline, also exhibits balanced action, but does not appear as effective in treating serotonin-mediated depression as imipramine.

Please see last page for a brief summary of the prescribing information.

anxiety-depression

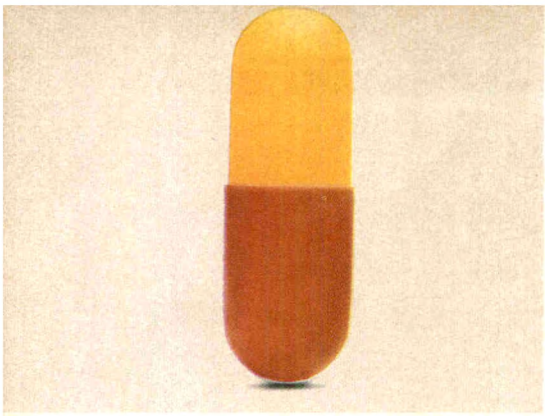
THE RIGH

Geigy

COMBINATION...

While Tofranil-PM alone exerts a sedative effect in depression, some patients with mixed anxiety-depression require the added control of a minor tranquilizer. For such patients, you can confidently prescribe diazepam (or virtually any other antianxiety agent) adjunctively with Tofranil-PM —unsurpassed among tricyclic antidepressants for its mood-brightening activity.[1, 2]

Tofranil-PM is effective when used alone or in combination regimens. Virtually any combination of psychotropics is possible—a flexibility difficult to achieve with fixed-combination antidepressant regimens.



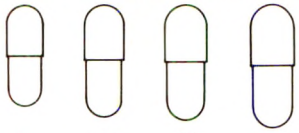
The decision of which drugs to combine, and at what dosages, remains entirely in your hands . . . where it belongs.

Please see last page for a brief summary of the prescribing information.

Tofranil-PM®...plus Valium® or any antianxiety agent

imipramine pamoate

(diazepam)



for many patients, the right antidepressant alone... or the basis of the right combination

Tofranil-PM® imipramine pamoate ...unsurpassed antidepressant action

For the majority of patients with neurotic depression, Tofranil-PM may be the only drug needed to produce a satisfactory brightening of mood.[1, 2] A recent report[4] notes that the two leading single-entity tricyclic antidepressants—imipramine pamoate (Tofranil-PM) and amitriptyline—provide equally effective antidepressant activity.

Better quality sleep—usually without morning "hangover"

Recent evaluation confirms that "... patients treated with imipramine pamoate tended ($P < .09$) to have a better quality of sleep than those treated with amitriptyline."[4]

75 mg 100 mg 125 mg 150 mg

Each capsule contains imipramine pamoate equivalent to 75, 100, 125 or 150 mg of imipramine hydrochloride.

Many patients show good results on Tofranil-PM 75 mg h.s.; however, the most effective daily dose may be the 150-mg capsule.

Tofranil-PM®

imipramine pamoate

Capsules of 75 mg.
Capsules of 100 mg.
Capsules of 125 mg.
Capsules of 150 mg.
For oral administration

Each 75-mg. capsule contains imipramine pamoate equivalent to 75 mg. of imipramine hydrochloride.
Each 100-mg. capsule contains imipramine pamoate equivalent to 100 mg. of imipramine hydrochloride.
Each 125-mg. capsule contains imipramine pamoate equivalent to 125 mg. of imipramine hydrochloride.
Each 150-mg. capsule contains imipramine pamoate equivalent to 150 mg. of imipramine hydrochloride.

Brief Summary of Prescribing Information

Indications For the relief of symptoms of depression. Endogenous depression is more likely to be alleviated than other depressive states.

Contraindications The concomitant use of monoamine oxidase inhibiting compounds is contraindicated. Hyperpyretic crises or severe convulsive seizures may occur in patients receiving such combinations. The potentiation of adverse effects can be serious, or even fatal. When it is desired to substitute Tofranil-PM, brand of imipramine pamoate, in patients receiving a monoamine oxidase inhibitor, as long an interval should elapse as the clinical situation will allow, with a minimum of 14 days. Initial dosage should be low and increases should be gradual and cautiously prescribed.
The drug is contraindicated during the acute recovery period after a myocardial infarction. Patients with a known hypersensitivity to this compound should not be given the drug. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind.

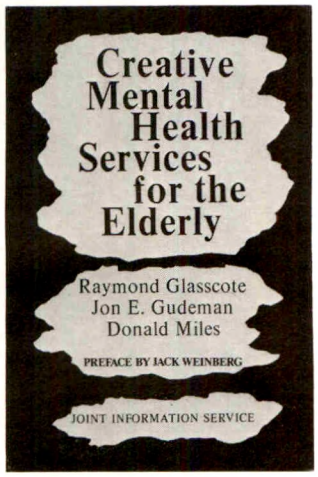
Warnings *Usage in Pregnancy:* Safe use of imipramine during pregnancy and lactation has not been established; therefore, in administering the drug to pregnant patients, nursing mothers, or women of childbearing potential, the potential benefits must be weighed against the possible hazards. Animal reproduction studies have yielded inconclusive results. There have been clinical reports of congenital malformation associated with the use of imipramine, but a causal relationship has not been confirmed.
Extreme caution should be used when this drug is given to:

- patients with cardiovascular disease because of the possibility of conduction defects, arrhythmias, myocardial infarction, strokes and tachycardia;
- patients with increased intraocular pressure, history of urinary retention, or history of narrow-angle glaucoma because of the drug's anticholinergic properties;
- hyperthyroid patients or those on thyroid medication because of the possibility of cardiovascular toxicity;
- patients with a history of seizure disorder because this drug has been shown to lower the seizure threshold;
- patients receiving guanethidine or similar agents since Tofranil-PM, brand of imipramine pamoate, may block the pharmacologic effects of these drugs.

Since imipramine may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks, such as operating an automobile or machinery, the patient should be cautioned accordingly.
Usage in Children: Tofranil-PM, brand of imipramine pamoate, should not be used in children of any age because of the increased potential for acute overdosage due to the high unit potency (75 mg., 100 mg., 125 mg. and 150 mg.). Each capsule contains imipramine pamoate equivalent to 75 mg., 100 mg., 125 mg. or 150 mg. imipramine hydrochloride.

Precautions It should be kept in mind that the possibility of suicide in seriously depressed patients is inherent in the illness and may persist until significant remission occurs. Such patients should be carefully supervised during the early phase of treatment with Tofranil-PM, brand of imipramine pamoate, and may require hospitalization. Prescriptions should be written for the smallest amount feasible.
Hypomanic or manic episodes may occur, particularly in patients with cyclic disorders. Such reactions may necessitate discontinuation of the drug. If needed, Tofranil-PM, brand of imipramine pamoate, may be resumed in lower dosage when these ep relieved. Administration of a tranquilizer ful in controlling such episodes.
Prior to elective surgery, imipramine shoul tinued for as long as the clinical situation
An activation of the psychosis may occa observed in schizophrenic patients and reduction of dosage and the addition of phenothiazine.
In occasional susceptible patients or in t ing anticholinergic drugs (including antip agents) in addition, the atropine-like effe come more pronounced (e.g., paralytic i supervision and careful adjustment of dc quired when this drug is administered co with anticholinergic or sympathomimetic
Avoid the use of preparations, such as d and local anesthetics, which contain any pathomimetic amine (e.g., adrenalin, nor since it has been reported that tricyclic a sants can potentiate the effects of catec
Patients should be warned that the conc of alcoholic beverages may be associate exaggerated effects.
Both elevation and lowering of blood suc have been reported.
Concurrent administration of imipramine troshock therapy may increase the haza treatment should be limited to those pati whom it is essential, since there is limite experience.

Adverse Reactions Note: Although the follows includes a few adverse reactions not been reported with this specific drug macological similarities among the tricyc depressant drugs require that each of th be considered when imipramine is admi
Cardiovascular: Hypotension, hypertens dia, palpitation, myocardial infarction, ar heart block, stroke, falls.
Psychiatric: Confusional states (especia derly) with hallucinations, disorientation, anxiety, restlessness, agitation; insomnia mares; hypomania; exacerbation of psy
Neurological: Numbness, tingling, pares tremities; incoordination, ataxia, tremors neuropathy; extrapyramidal symptoms; alterations in EEG patterns; tinnitus.
Anticholinergic: Dry mouth, and, rarely, a sublingual adenitis; blurred vision, distu accommodation, mydriasis; constipation ileus; urinary retention, delayed micturiti the urinary tract.
Allergic: Skin rash, petechiae, urticaria, photosensitization (avoid excessive exp light); edema (general or of face and tor fever; cross-sensitivity with desipramine
Hematologic: Bone marrow depression agranulocytosis; eosinophilia; purpura; cytopenia. Leukocyte and differential cc be performed in any patient who develc sore throat during therapy; the drug shc continued if there is evidence of patholc phil depression.
Gastrointestinal: Nausea and vomiting, epigastric distress, diarrhea; peculiar ta abdominal cramps, black tongue.
Endocrine: Gynecomastia in the male; t largement and galactorrhea in the fema or decreased libido, impotence; testicul elevation or depression of blood sugar l
Other: Jaundice (simulating obstructive function; weight gain or loss; perspiratic urinary frequency; drowsiness, dizzines and fatigue; headache; parotid swelling
Withdrawal Symptoms: Though not indi addiction, abrupt cessation of treatmen longed therapy may produce nausea, h malaise.



How Supplied Tofranil-PM, brand of im pamoate, is available as follows:
75-mg., coral-colored capsules equival imipramine hydrochloride in bottles of 3 1,000 capsules.
100-mg., dark yellow/coral-colored cap alent to 100 mg. imipramine hydrochlori of 30, 100 and 1,000 capsules.
125-mg., light yellow/coral-colored cap lent to 125 mg. imipramine hydrochlorid 30, 100 and 1,000 capsules.
150-mg., coral-colored capsules equiva mg. imipramine hydrochloride in bottles and 1,000 capsules.

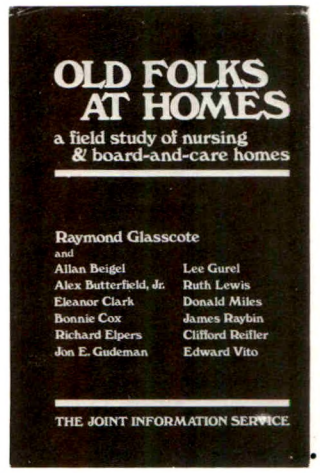
The Joint Information Service of the American Psychiatric Association and the Mental Health Association releases Two New Volumes That

Focus on the Elderly



This carefully documented book reports a field study of ten programs, four in America and six in England and Scandinavia, which serve as practical demonstrations of creative mental health services for the elderly. They include:

- a novel "Neighborhood Family" providing vigorous support to elderly residents of several trailer parks
- a high school for the elderly which sends its students abroad for study trips
- a "Human Development Project" that focuses on responding to the psychological needs of the elderly
- a carefully coordinated system of "respite hospitalization," which promotes the health of the elderly while allowing maximum use of hospital beds and family resources
- a "Lucy Booth," patterned after the Peanuts comic strip, which provides easy access to many kinds of services
- and many other innovative, successful approaches.

Each program is subjected to intensive scrutiny. The resulting document becomes a handbook, and, as well, a forum through which some of the world's most experienced practitioners of "the psychiatry of old age" present their views.

Dr. Wilma Donohue, director of the International Center for Social Gerontology, characterizes this volume as "a masterful job of putting everything in relief . . . the guidelines for action are right here."

190 pages. Casebound. Price $8.50.

Concerned about the very bad reputation that nursing homes have received from many quarters in recent years, the Joint Information Service set up a field study to visit a systematically chosen sample of nursing homes, and board-and-care homes as well, to see to what extent the care of and the quality of life for the patients differed from the geriatrics units of state hospitals. Altogether, sixty nursing homes and 31 board-and-care homes in ten locales were visited, in each case by the senior author accompanied by two mental health professionals.

The teams were surpised to learn that care and quality of life in many of the nursing and board-and-care homes they visited were better—sometimes dramatically better—than that in the mental health facilities and often at lower cost.

This unique publication provides an overview of all facilities visited plus vignettes of approximately half. Federal and state rules and regulations are also expertly synthesized into brief and readable style.

148 pages. Casebound. Price $6.50

Thought disorder, hallucinations and hostility managed
Sam T. is now asymptomatic with no sexual dysfunction or other major side effects.*

LOXITANE® Loxapine Succinate

Permits rapid management of Sam's hostility and excited behavior

Thirty-six year old salad maker, claiming to be the "Wild Man of the West" was brought to the hospital by his kitchen supervisor. History revealed prior psychiatric hospitalizations and therapies including psychotropic drugs. Hypertension was noted as a complication of earlier treatment with antipsychotic drugs. Diagnosis: chronic schizophrenia, acute exacerbation. He responded promptly to LOXITANE® C Loxapine HCl Concentrate 50 mg stat, followed by LOXITANE® Loxapine Succinate capsules 30 mg t.i.d.

Permits aggressive titration for rapid establishment of optimal management of Sam's thought disorder and hallucinations

During first week, LOXITANE dosage increased to 50 mg q.i.d. Significant improvement in thought disorder noted by third week. Auditory hallucinations and delusions much less frequent. Patient calmer and more cooperative.

Permits sustained symptom management with minimal risk of serious adverse effects, such as sexual dysfunction

Patient revealed that while on outpatient status, he failed to take his previously prescribed antipsychotic for a ten-month period after he met and married his girlfriend. He stated the drug "didn't let me be a man." No sexual dysfunction reported with LOXITANE.

Side effects are usually mild, transitory and easily managed

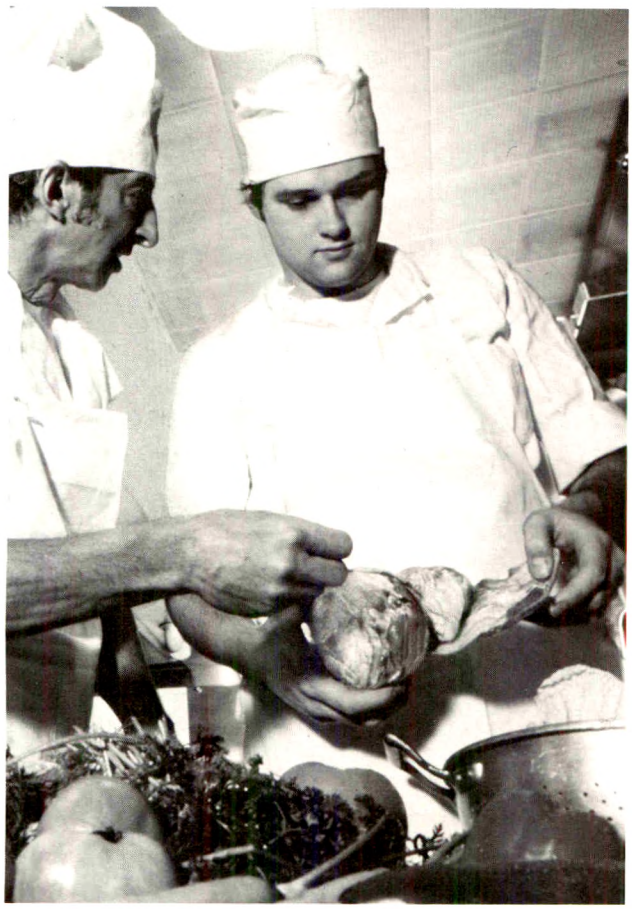
Patient felt anxious because his "heart was beating so fast," and he "could not sit still." Increased pulse rate and restlessness subsided following decrease of LOXITANE to 20 mg q.i.d.

Consistence in schizophrenic symptom management and tolerance promotes patient compliance

All admitting symptomatology under control by the fourth week. By the sixth week, he was anxious to return home. Stated "this medicine doesn't make me feel drowsy like the other did." Discharged by the eighth week. He returned to work fully managed on LOXITANE 20 mg t.i.d., and free from recurrence of previously reported side effects.

*Painful ejaculation and urine containing sperm have not been reported. Endocrine disturbances such as galactorrhea and menstrual irregularities have only been rarely reported. Other sexual side effects infrequently reported. Although not reported to date, possibility of hepatic, renal, ocular, or phototoxicity cannot be ruled out at this time. Transient liver enzyme changes not definitely related to LOXITANE have been reported. Not an actual patient, but a simulation to illustrate the action of LOXITANE as reported in clinical studies.

See LOXITANE prescribing information on following page for indications, warnings and precautions and for more detailed information concerning side effects.

Loxitane®


LOXAPINE SUCCINATE
Lederle

Recommended Daily Dosage

Initial Dosage	MILD 10 mg b.i.d.	MODERATE 10 mg t.i.d or q.i.d.	SEVERE 25 mg b.i.d.
First 7 to 10 days	Increase dosage until psychotic symptoms are controlled. Dosage should not exceed 250 mg/day. Usual dosage during titration: 50 to 150 mg/day.		
Maintenance Dosage	Adjust to lowest effective level. Usual maintenance dosage: 60 to 100 mg/day. Many patients are controlled with dosages as low as 20 to 60 mg/day.		

Brief Summary
LOXITANE® Loxapine Succinate Capsules
LOXITANE® C Loxapine Hydrochloride Oral Concentrate
INDICATIONS: Manifestations of schizophrenia.
CONTRAINDICATIONS: Comatose or severely depressed states; hypersensitivity to the drug.
WARNINGS: Safe use during pregnancy or lactation has not been established; weigh potential benefits to possible hazards. Not recommended for use in children under 16. May impair mental and/or physical abilities especially during early therapy; warn ambulatory patients about activities requiring alertness and concomitant use of alcohol or other CNS depressants. Not recommended for management of behavioral complications in mentally retarded patients.
PRECAUTIONS: Use with extreme caution in patients with a history of convulsive disorders; use with caution in patients with cardiovascular disease or in those with glaucoma or a tendency to urinary retention particularly when on concomitant anticholinergic medication. Loxapine has an antiemetic effect in animals which might occur in man masking signs of overdosage of toxic drugs and obscuring intestinal obstruction or brain tumor. Since possible ocular toxicity cannot be excluded, observe carefully for pigmentary retinopathy and lenticular pigmentation.
ADVERSE REACTIONS: CNS effects, other than extrapyramidal, infrequent. Mild drowsiness may occur at beginning of therapy or upon dosage increase, usually subsides with continued therapy. Sedation, dizziness, faintness, staggering gait, muscle twitching, weakness and confusional states have been reported. Extrapyramidal reactions often occur early in treatment manifested by Parkinson-like symptoms (tremor, rigidity, excessive salivation, masked facies, akathisia) controllable by dosage reduction or antiparkinson drugs at usual dosages. Dystonic and dyskinetic reactions, while less frequently occurring, may be more severe, requiring dosage reduction or temporary withdrawal plus appropriate counteractive drugs. Persistent Tardive Dyskinesia may appear during prolonged therapy or following discontinuance, the risk greater in the elderly, especially females, on high dosage. Symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of the tongue, face, mouth and jaw sometimes accompanied by involuntary movement of extremities. Since there is no known effective treatment, discontinue all antipsychotic drugs if symptoms appear. Reinstitution of treatment, increased dosage, or switching to another agent may mask syndrome. The syndrome may not develop if medication is stopped when fine vermicular movements of the tongue first appear. Cardiovascular Effects: Tachycardia, hypotension, hypertension, lightheadedness and syncope. ECG changes, not known to be related to loxapine use, have been reported. Skin: Dermatitis, edema of face, pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of unknown etiology seen in a few patients in hot summer months. Anticholinergic: Dry mouth, nasal congestion, constipation, blurred vision (more likely to occur with concomitant use of antiparkinson agents). Other: Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of unknown etiology.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The tota daily dosage, up to 150 mg per day, may be giver on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly o served side effect. Dry mouth, blurred vision, consti pation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severi starting daily dose of 75 mg is recommended. Dosage may subsequently be increase decreased at appropriate intervals and according to individual response. The usual optir dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increa 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceedi dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying org disease, lower doses may suffice. Some of these patients have been controlled on doses as as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a dosage schedule. If the once-a-day schedule is employed the maximum recommended do 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intende maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant e may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.

2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ile hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.

2. Severe: Medical management of severe SINEQUAN overdosage consists of aggres supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautior prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absor The use of activated charcoal has been recommended, as has been continuous gastric la with saline for 24 hours or more. An adequate airway should be established in comatose pati and assisted ventilation used if necessary. EKG monitoring may be required for several c since relapse after apparent recovery has been reported. Arrhythmias should be treated with appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow in venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmin rapidly metabolized, the dosage should be repeated as required. Convulsions may respor standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory dep sion. Dialysis and forced diuresis generally are not of value in the management of overdos due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibr at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 1(doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prur pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a numb carbonated beverages. For those patients requiring antidepressant therapy who ar methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be m together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not grape juice. Preparation and storage of bulk dilutions is not recommended.

More detailed professional information available on request.

Pfizer LABORATORIES DIVISION
PFIZER INC.

The American Psychiatric Association announces publication of two volumes reporting the Conference on Education of Psychiatrists

held at Lake of the Ozarks, Missouri, June 9-15, 1975. Organized by the A.P.A. in cooperation with the American Academy of Child Psychiatry, the American Association of Chairmen of Departments of Psychiatry, and the American Association of Directors of Psychiatric Residency Training.

1. PSYCHIATRIC EDUCATION: PROLOGUE TO THE 1980's, Library Bound, 544 pages, $15.00.

This is a substantive, highly readable, report of the Conference, written by Anne H. Rosenfeld with an Editorial Board comprising: Ewald W. Busse, M.D., Chairperson of the Conference, Walter E. Barton, M.D., Bernard Holland, M.D., Donna Norris, M.D., Melvin Sabshin, M.D., Jeanne Spurlock, M.D., and Robert L. Robinson, M.A. (Staff Consultant).

The volume contains ten chapters covering the topical structure of the Conference: Goals and Values; Competence, Evaluation, and Quality Control; The Resident; Faculty; Educational Methods: Means in the Service of Ends; The Program Environment; Research; The Economics of Residency Training; Psychiatry in Its Social Context; and Retrospect and Prospect. It also contains nine appendices describing the organization of the Conference and its participants, together with selected model programs and related informational materials of value.

2. THE WORKING PAPERS OF THE 1975 CONFERENCE ON EDUCATION OF PSYCHIATRISTS Paper bound, 432 pages, $12.50.

Sixty two leading psychiatric educators served on seven preparatory commissions, one for each of seven topic areas, and prepared advance working papers as a basis for Conference deliberations. The topics and Commission Chairpersons were: Social Issues and Needs (James N. Sussex, M.D.); Goals and Objectives (Morton F. Reiser, M.D.); The Resident (David R. Hawkins, M.D.); Content, Methodology, Faculty and Environment (Milton Greenblatt, M.D.); Research (Daniel X. Freedman, M.D.); Economics (Herzl Spiro, M.D.); Evaluation and Quality Control (Eric Pfeiffer, M.D.). The Chairpersons, together with the Conference Chairperson, served as the Editorial Board for this volume.

Papers commenting on the reports of the commissions, published here for the first time, were presented at the Conference by Melvin Sabshin, M.D., Eugene B. Brody, M.D., Jeanne Spurlock, M.D., Jack R. Ewalt, M.D., Robert J. Stoller, M.D., James R. Comer, M.D., and Bernard Holland, M.D.

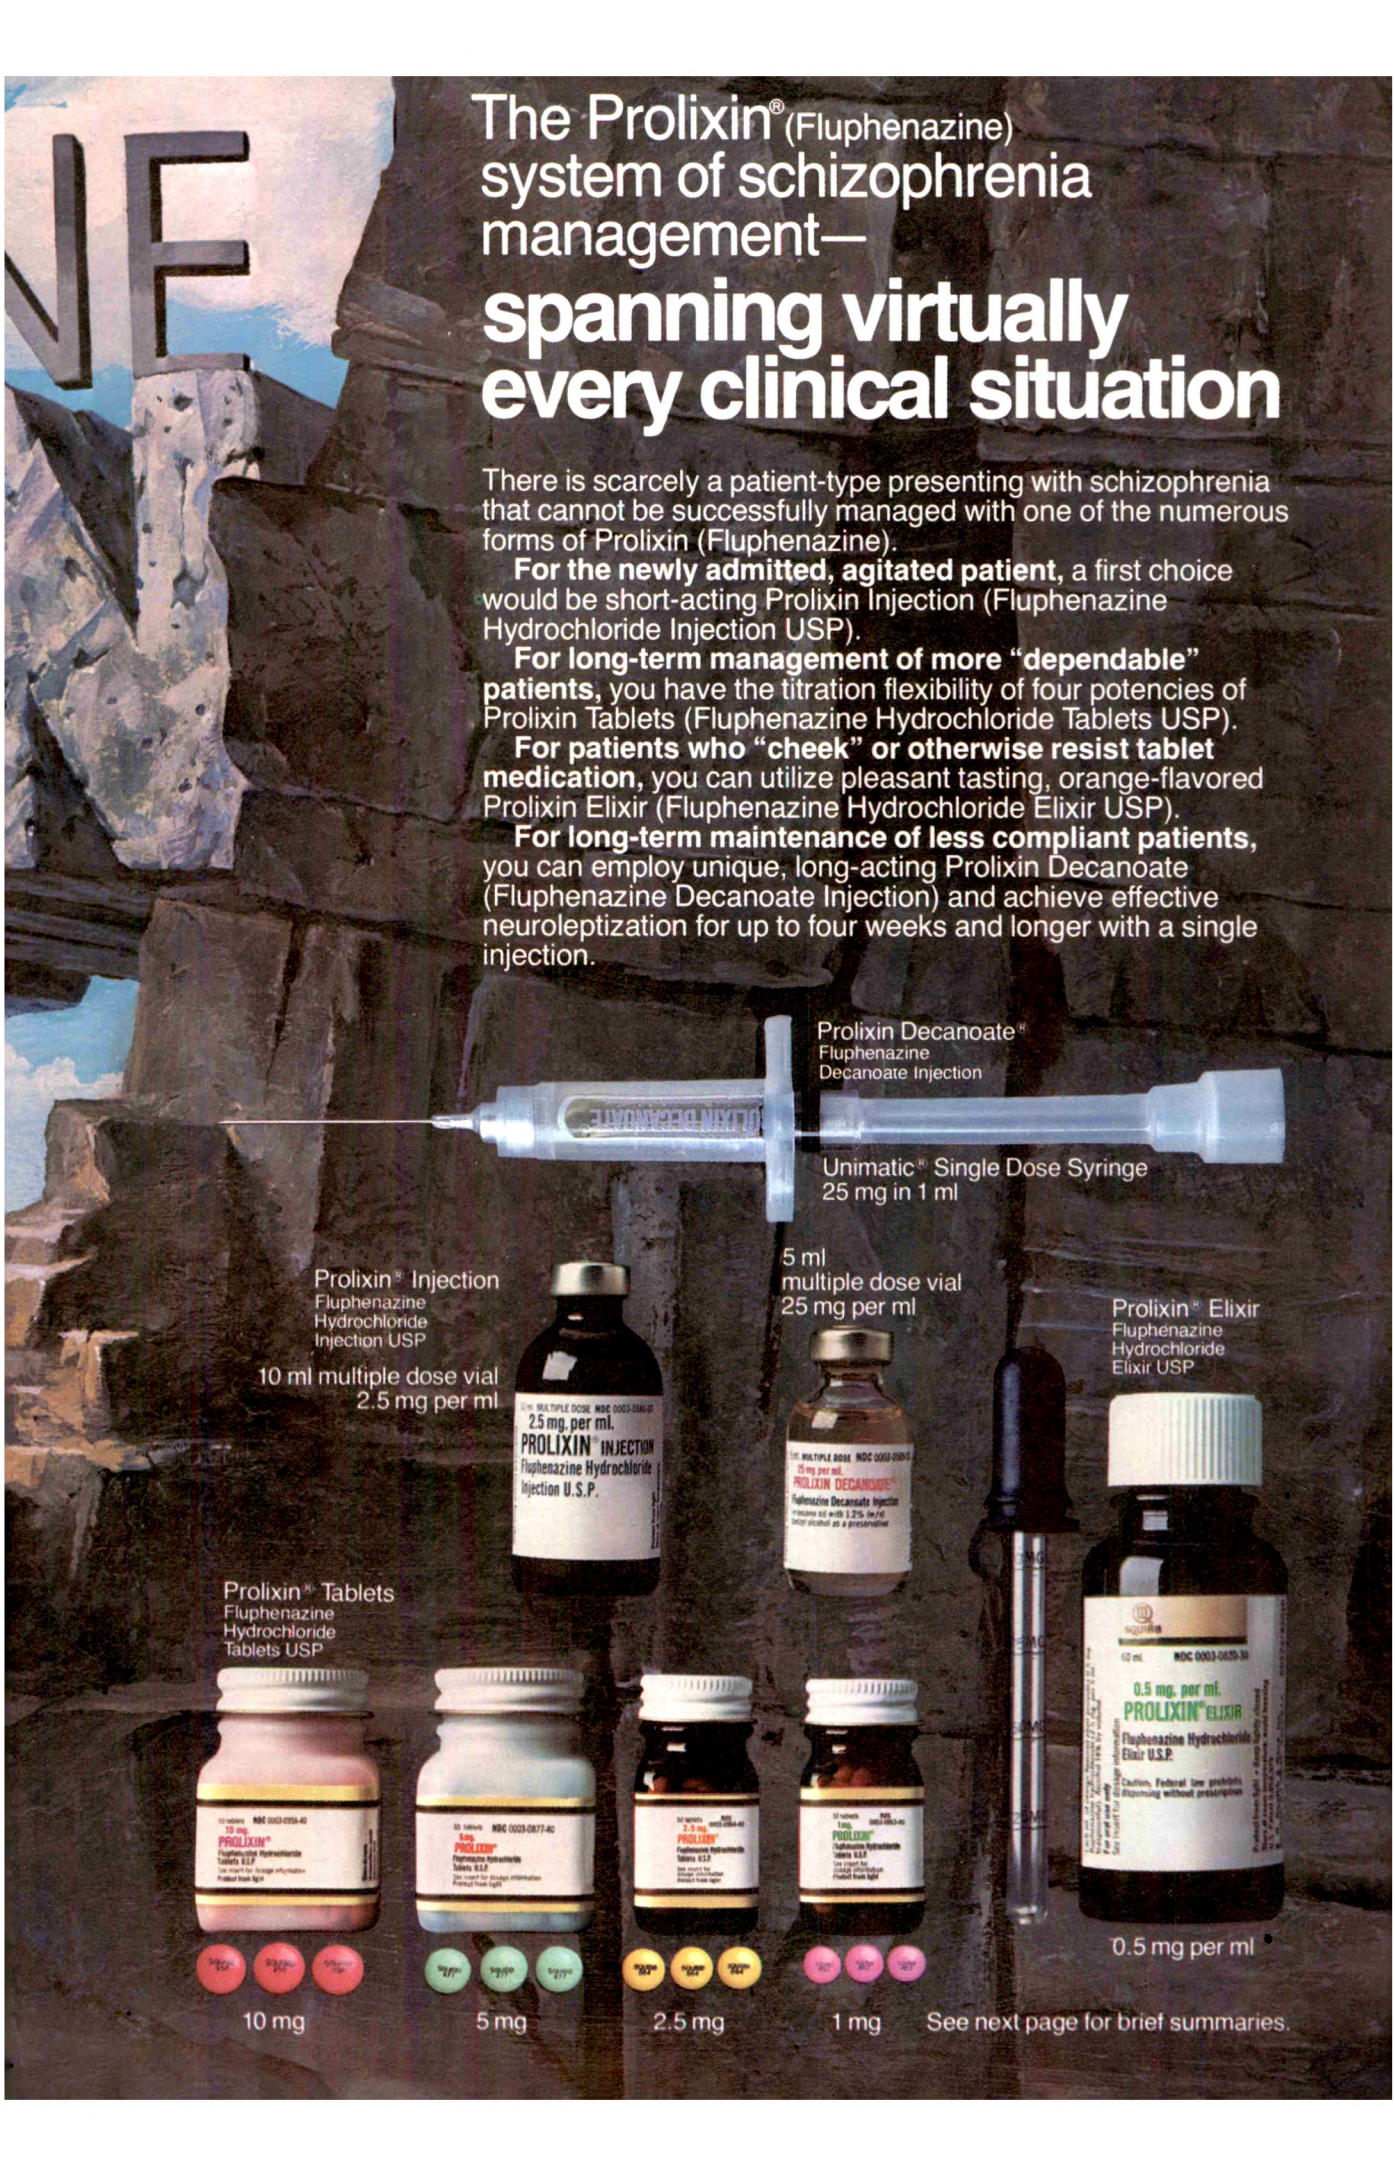
FLUORHENAZ
PROLIX

The Prolixin® (Fluphenazine) system of schizophrenia management—

spanning virtually every clinical situation



There is scarcely a patient-type presenting with schizophrenia that cannot be successfully managed with one of the numerous forms of Prolixin (Fluphenazine).

For the newly admitted, agitated patient, a first choice would be short-acting Prolixin Injection (Fluphenazine Hydrochloride Injection USP).

For long-term management of more "dependable" patients, you have the titration flexibility of four potencies of Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP).

For patients who "cheek" or otherwise resist tablet medication, you can utilize pleasant tasting, orange-flavored Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP).

For long-term maintenance of less compliant patients, you can employ unique, long-acting Prolixin Decanoate (Fluphenazine Decanoate Injection) and achieve effective neuroleptization for up to four weeks and longer with a single injection.

See next page for brief summaries.

PROLIXIN® (Fluphenazine Hydrochloride)
TABLETS/ELIXIR/INJECTION

Prolixin Tablets (Fluphenazine Hydrochloride Tablets USP) provide 1, 2.5, 5, or 10 mg fluphenazine hydrochloride per tablet. Prolixin Elixir (Fluphenazine Hydrochloride Elixir USP) provides 0.5 mg fluphenazine hydrochloride per ml (2.5 mg per 5 ml teaspoonful) with 14% alcohol by volume. Prolixin Injection (Fluphenazine Hydrochloride Injection USP) provides 2.5 mg fluphenazine hydrochloride per ml; it contains 0.1% methylparaben and 0.01% propylparaben as preservatives.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain damage. In patients who have a blood dyscrasia or liver damage, or who are receiving large doses of hypnotics, or who are comatose or severely depressed. In patients who have shown hypersensitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

WARNINGS: Mental and physical abilities required for driving a car or operating heavy machinery may be impaired by use of this drug. Potentiation of effects of alcohol may occur. Safety and efficacy in children have not been established because of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; weigh possible hazards against potential benefits if administering this drug to pregnant patients.

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused cholestatic jaundice, dermatoses or other allergic reactions because of the possibility of cross-sensitivity. When psychotic patients on large doses of a phenothiazine drug are to undergo surgery, hypotensive phenomena should be watched for; less anesthetics or central nervous system depressants may be required. Because of added anticholinergic effects, fluphenazine may potentiate the effects of atropine.

Use fluphenazine cautiously in patients exposed to extreme heat or phosphorus insecticides; in patients with a history of convulsive disorders since grand mal convulsions have occurred; and in patients with special medical disorders such as mitral insufficiency or other cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged therapy there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal deposits, and development of irreversible dyskinesia.

There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to fluphenazine hydrochloride and other antipsychotic drugs is not known.

Periodic checking of hepatic and renal functions and blood picture should be done. Monitor renal function of patients on long-term therapy; if BUN becomes abnormal, discontinue fluphenazine. "Silent pneumonias" are possible.

Abrupt Withdrawal: In general, phenothiazines do not produce psychic dependence. However, gastritis, nausea and vomiting, dizziness, and tremulousness have been reported following abrupt cessation of high dose therapy; reports suggest that these symptoms can be reduced if concomitant antiparkinsonian agents are continued for several weeks after the phenothiazine is withdrawn.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are most frequently reported. Most often these symptoms are reversible, but they may be persistent. They include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opisthotonos, hyperreflexia. The incidence and severity of such reactions will depend more on individual patient sensitivity, but dosage level and patient age are also determinants. As these reactions may be alarming, the patient should be forewarned and reassured. These reactions can usually be controlled by administration of an anti-parkinsonian drug such as benztropine mesylate and by subsequent reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and sometimes irreversible tardive dyskinesia may appear in some patients on long-term therapy or may occur after discontinuation of drug. The risk seems greater in elderly patients, especially females, on high dosages. The syndrome is characterized by rhythmical involuntary movements of tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and may be accompanied by involuntary movements of extremities. There is no known effective therapy for tardive dyskinesia; usually the symptoms are not alleviated by antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic agents is suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage increased, or a different antipsychotic agent used. Reports are that fine vermicular movements of the tongue may be an early sign of the syndrome which may not develop if medication is stopped at that time.

Phenothiazine derivatives have been known to cause restlessness, excitement, or bizarre dreams; reactivation or aggravation of psychotic processes may be encountered. If drowsiness or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the recommended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have been reported. Although hypotension is rarely a problem, patients with pheochromocytoma, cerebral vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insufficiency appear to be particularly prone to this reaction and should be observed carefully. Supportive measures including intravenous vasopressor drugs should be instituted immediately should severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epinephrine should not be used* since phenothiazine derivatives have been found to reverse its action. Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and constipation may occur. Reducing or temporarily discontinuing the dosage will usually control these effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachycardia, or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lactation, gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in men and increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczema and exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphylactoid reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytopenic or nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observed with phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper respiratory infection occur and confirmatory leukocyte count indicates cellular depression, therapy should be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during the first months of therapy, may occur; treatment should be discontinued. A cephalin flocculation increase, sometimes accompanied by alterations in other liver function tests, has been reported in patients who have had no clinical evidence of liver damage.

Others—Sudden deaths have been reported in hospitalized patients on phenothiazines. Previous brain damage or seizures may be predisposing factors. High doses should be avoided in known seizure patients. Shortly before death, several patients showed flare-ups of psychotic behavior patterns. Autopsy findings have usually revealed acute fulminating pneumonia or pneumonitis, aspiration of gastric contents, or intramyocardial lesions. Although not a general feature of fluphenazine, potentiation of central nervous system depressants such as opiates, analgesics, antihistamines, barbiturates, and alcohol may occur.

Systemic lupus erythematosus-like syndrome, hypotension severe enough to cause fatal cardiac arrest, altered electrocardiographic and electroencephalographic tracings, altered cerebrospinal fluid proteins, cerebral edema, asthma, laryngeal edema, and angioneurotic edema; with long-term use, skin pigmentation and lenticular and corneal opacities have occurred with phenothiazines.

For full prescribing information, consult package inserts.

HOW SUPPLIED: *Tablets*—1 mg in bottles of 50 and 500; 2.5 mg and 5 mg in bottles of 50 and 500 and in Unimatic® single-dose cartons of 100; 10 mg in bottles of 50 and 500. *Elixir*—in bottles of 473 ml (1 pint) and in 60 ml dropper-assembly bottles with dropper calibrated at 0.5 ml (0.25 mg), 1 ml (0.5 mg), 1.5 ml (0.75 mg), and 2 ml (1 mg). *Injection*—in multiple-dose vials of 10 ml.

PROLIXIN DECANOATE®
Fluphenazine Decanoate Injection

Prolixin Decanoate (Fluphenazine Decanoate Injection) provides 25 mg fluphenazine deca per ml in a sesame oil vehicle with 1.2% (w/v) benzyl alcohol as a preservative.

CONTRAINDICATIONS: In presence of suspected or established subcortical brain dama patients who have a blood dyscrasia or liver damage, or who are receiving large dos hypnotics, or who are comatose or severely depressed. In patients who have shown hype sitivity to fluphenazine; cross-sensitivity to phenothiazine derivatives may occur.

Not intended for use in children under 12.

WARNINGS: Mental and physical abilities required for driving a car or operating heav chinery may be impaired by use of this drug. Physicians should be alert to the possibilit severe adverse reactions may occur which require immediate medical attention. Potentia effects of alcohol may occur. Safety and efficacy in children have not been established be of inadequate experience in use in children.

Usage in Pregnancy: Safety for use during pregnancy has not been established; possible hazards against potential benefits if administering this drug to pregnant patier

PRECAUTIONS: Caution must be exercised if another phenothiazine compound caused c tatic jaundice, dermatoses or other allergic reactions because of the possibility of sensitivity. When psychotic patients on large doses of a phenothiazine drug are to un surgery, hypotensive phenomena should be watched for; less anesthetics or central ne system depressants may be required. Because of added anticholinergic effects, flupher may potentiate the effects of atropine.

Use fluphenazine decanoate cautiously in patients exposed to extreme heat or phosp insecticides; in patients with a history of convulsive disorders since grand mal convulsions occurred; and in patients with special medical disorders such as mitral insufficiency or cardiovascular diseases, and pheochromocytoma. Bear in mind that with prolonged th there is the possibility of liver damage, pigmentary retinopathy, lenticular and corneal dep and development of irreversible dyskinesia.

Fluphenazine decanoate should be administered under the direction of a physician e enced in the clinical use of psychotropic drugs. Periodic checking of hepatic and renal fun and blood picture should be done. Renal function of patients on long-term therapy sho monitored; if BUN becomes abnormal, treatment should be discontinued. "Silent pneum are possible.

There is sufficient experimental evidence to conclude that chronic administration of a chotic drugs which increase prolactin secretion has the potential to induce mammary neop in rodents under the appropriate conditions. There are recognized differences in the phy ical role of prolactin between rodents and humans. Since there are, at present, no ade epidemiological studies, the relevance to human mammary cancer risk from prolonged exp to fluphenazine decanoate and other antipsychotic drugs is not known.

ADVERSE REACTIONS: *Central Nervous System*—Extrapyramidal symptoms are mo quently reported. Most often these symptoms are reversible, but they may be persistent include pseudoparkinsonism, dystonia, dyskinesia, akathisia, oculogyric crises, opistho hyperreflexia. Muscle rigidity sometimes accompanied by hyperthermia has been re withdrawal of fluphenazine decanoate. One can expect a higher incidence of such rea with fluphenazine decanoate than with less potent piperazine derivatives or straight phenothiazines. The incidence and severity will depend more on individual patient sensitiv dosage level and patient age are also determinants. As these reactions may be alarmir patient should be forewarned and reassured. These reactions can usually be control administration of an antiparkinsonian drug such as benztropine mesylate and by subse reduction in dosage.

Persistent Tardive Dyskinesia: As with all antipsychotic agents, persistent and som irreversible tardive dyskinesia may appear in some patients on long-term therapy or may after discontinuation of drug. The risk seems greater in elderly patients, especially fema high dosages. The syndrome is characterized by rhythmical involuntary movements of t face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, ch movements) and may be accompanied by involuntary movements of extremities. There known effective therapy for tardive dyskinesia; usually the symptoms are not allevia antiparkinsonism agents. If the symptoms appear, discontinuation of all antipsychotic ag suggested. The syndrome may be masked if treatment is reinstituted, or drug dosage incr or a different antipsychotic agent used. Reports are that fine vermicular movements of the may be an early sign of the syndrome which may not develop if medication is stopped at tha

Phenothiazine derivatives have been known to cause restlessness, excitement, or dreams; reactivation or aggravation of psychotic processes may be encountered. If drow or lethargy occur, the dosage may need to be reduced. Dosages, far in excess of the mended amounts, may induce a catatonic-like state.

Autonomic Nervous System—Hypertension and fluctuations in blood pressure have reported. Although hypotension is rarely a problem, patients with pheochromocytoma, vascular or renal insufficiency or severe cardiac reserve deficiency such as mitral insuffi appear to be particularly prone to this reaction and should be observed carefully. Sup measures including intravenous vasopressor drugs should be instituted immediately severe hypotension occur; Levarterenol Bitartrate Injection is the most suitable drug; *epine should not be used* since phenothiazine derivatives have been found to reverse its Nausea, loss of appetite, salivation, polyuria, perspiration, dry mouth, headache and co tion may occur. Reducing or temporarily discontinuing the dosage will usually contro effects. Blurred vision, glaucoma, bladder paralysis, fecal impaction, paralytic ileus, tachy or nasal congestion have occurred in some patients on phenothiazine derivatives.

Metabolic and Endocrine—Weight change, peripheral edema, abnormal lac gynecomastia, menstrual irregularities, false results on pregnancy tests, impotency in m increased libido in women have occurred in some patients on phenothiazine therapy.

Allergic Reactions—Itching, erythema, urticaria, seborrhea, photosensitivity, eczem exfoliative dermatitis have been reported with phenothiazines. The possibility of anaphy reactions should be borne in mind.

Hematologic—Blood dyscrasias including leukopenia, agranulocytosis, thrombocytop nonthrombocytopenic purpura, eosinophilia, and pancytopenia have been observe phenothiazines. If soreness of the mouth, gums or throat or any symptoms of upper resp infection occur and confirmatory leukocyte count indicates cellular depression, therapy be discontinued and other appropriate measures instituted immediately.

Hepatic—Liver damage manifested by cholestatic jaundice, particularly during t months of therapy, may occur; treatment should be discontinued. MANUAL OF PSYCHIATRIC PEER REVIEW

by the Peer Review Committee of the American Psychiatric Association, Donald G. Langsley, M.D., Chairperson in cooperation with the Joint Task Force on Diagnostic Criteria for Analyzability of the American Psychoanalytic Association, William Offenkrantz, M.D., Chairperson, and the Peer Review Committee of the American Academy of Child Psychiatry. Larry B. Silver, M.D., Chairperson.

"This Manual provides a set of guidelines for district branches of APA and their peer review committees which should be adapted and modified in terms of local criteria, standards, and practices. The guidelines are not intended to be hard and fast rules. They are screening criteria, and not regulations to control practice. They are so designed that they can be utilized by non-physicians to identify those cases that can profitably be reviewed by psychiatrists serving on peer review committees. This document should be viewed as transitional, subject to revision as experience is gained, and continually updated in response to advances in psychiatric knowledge and changes in patterns of practice. . . . The application of these standards, and refinement through experience must rest with the peer review committees of district branches. . . . It should help them to move ahead in the development of a peer review for American psychiatry."

Robert W. Gibson, M.D.
President

Part I titled PSYCHIATRIC PEER REVIEW contains sections on Basic Relationships and Responsibilities, Appointment of Peer Review Committees, Funding, Operations and Procedures, Medical Care Evaluation Studies, Appeals Processes, Special Problems, Confidentiality, Educational Aspects, Medical Ethics, Advocacy, Interdisciplinary Aspects, with Appendices on Model Screening Format for Inpatient Treatment for Alcoholism, Model Screening Format for Outpatient Treatment, Sample Form for Requesting Extension of Office Treatment, Claims Review Guidelines Suggestions, APA Position Papers on Peer Review, Bibliography.

Part II titled PSYCHOANALYTIC PEER REVIEW has sections on Steps in Peer Review for Psychoanalysis, Guidelines for Model Criteria Sets, Pilot Application of Guidelines for Model Criteria Sets, Sample Peer Review Form, Sample data from Pilot Applications of Guidelines, and Glossary of Terms Used.

Part III titled PEER REVIEW AND CHILD PSYCHIATRY contains sections of Special Considerations, Legal Rights of Children, Issue of Confidentiality, Conclusions, References, and Appendices on Model Screen Criteria Format for Intermediate Care, for Acute Care in a Short Stay Facilities, and for Partial Hospitalization, Outpatient Diagnostic Evaluation Procedures, and Outpatient Treatment for Children and Adolescents.

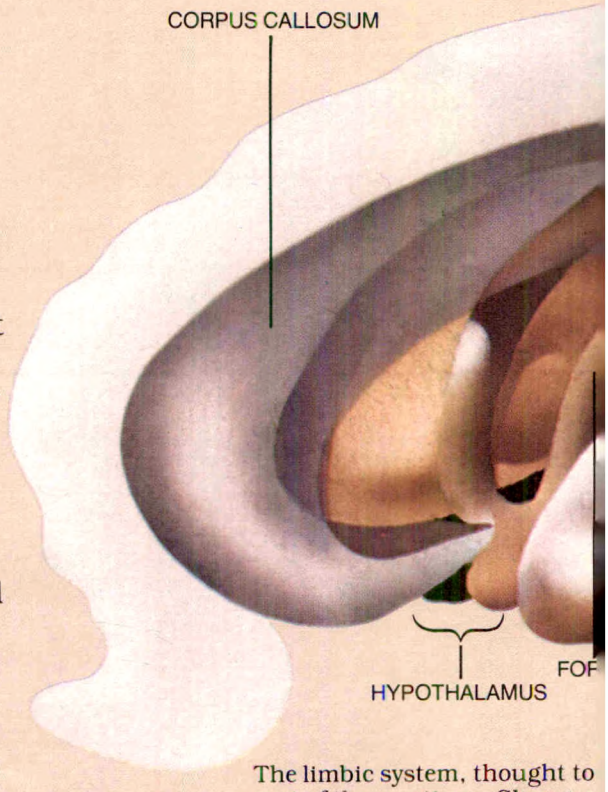
ANXIETY

SIMPLE SYMPTOM OR SYNDROME



Some psychiatrists consider anxiety a simple symptom complex

Some psychiatrists maintain that anxiety is a self-limiting symptomatic reaction to stressful circumstances, whether physical or psychological, that occurs when the magnitude of the stress surpasses the patient's ability to cope. Most stressors are a form of loss, but in some patients just the anticipation of loss can be emotionally disabling. Anxiety is the response when the patient's internal milieu is threatened by change, whether it is perceived as desirable or undesirable.[1]

1. *Stress Without Distress.* Hans Selye, interviewed by McCrie R: *Pract Psychol for Physicians* 3:52-56, Aug 1976

Others suggest it is a syndrome, a true disorder[2]

Psychiatrists who view anxiety as syndrome theorize that its etiolog and/or maintenance is primarily pendent on events within the cen nervous system. They point out t certain individuals appear to be i ently more anxiety prone than others—seem not only to perceive wider range of situations as threa ing but to respond to these situat with more pronounced levels of C arousal and subjective anxiety. O searcher,[3] who makes a sharp dis

ier MAB, Crandall PH, Walsh GO: *Exp* 51:241-258, Apr 1976

Symptom or syndrome, anxiety responds to Valium (diazepam)

When a patient's coping mechanisms are insufficient to deal with his level of anxiety, Valium (diazepam) can promptly and effectively relieve the anxiety and its somatic symptoms. Initial calming often occurs in hours. After several days of Valium therapy, anxiety relief is pronounced and sustained. And as the anxiety is reduced, accompanying tension, insomnia-like symptoms and somatic symptoms are also relieved.

Available in three scored tablet strengths, Valium allows you to set, adjust and readjust dosage as appropriate. For patients prone to anxiety at bedtime, you may want to add an *h.s.* dose to a *b.i.d.* or *t.i.d.* regimen.

Valium is usually well tolerated; side effects more severe than drowsiness, fatigue or ataxia are rare. As with all CNS-acting medications, patients should be cautioned against drinking alcohol or operating dangerous machinery while on Valium therapy. Periodic reassessment of the need for Valium is recommended.

VALIUM® (diazepam) IV

2-mg, 5-mg, 10-mg scored tablets

UNTIL THE PATIENT CAN COPE AGAIN

Please see following page for a summary of product information.

VALIUM® (diazepam)

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Tension and anxiety states; somatic complaints which are concomitants of emotional factors; psychoneurotic states manifested by tension, anxiety, apprehension, fatigue, depressive symptoms or agitation; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).

The effectiveness of Valium (diazepam) in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms (similar to those with barbiturates and alcohol) have occurred following abrupt discontinuance (convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Tension, anxiety and psychoneurotic states, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10.

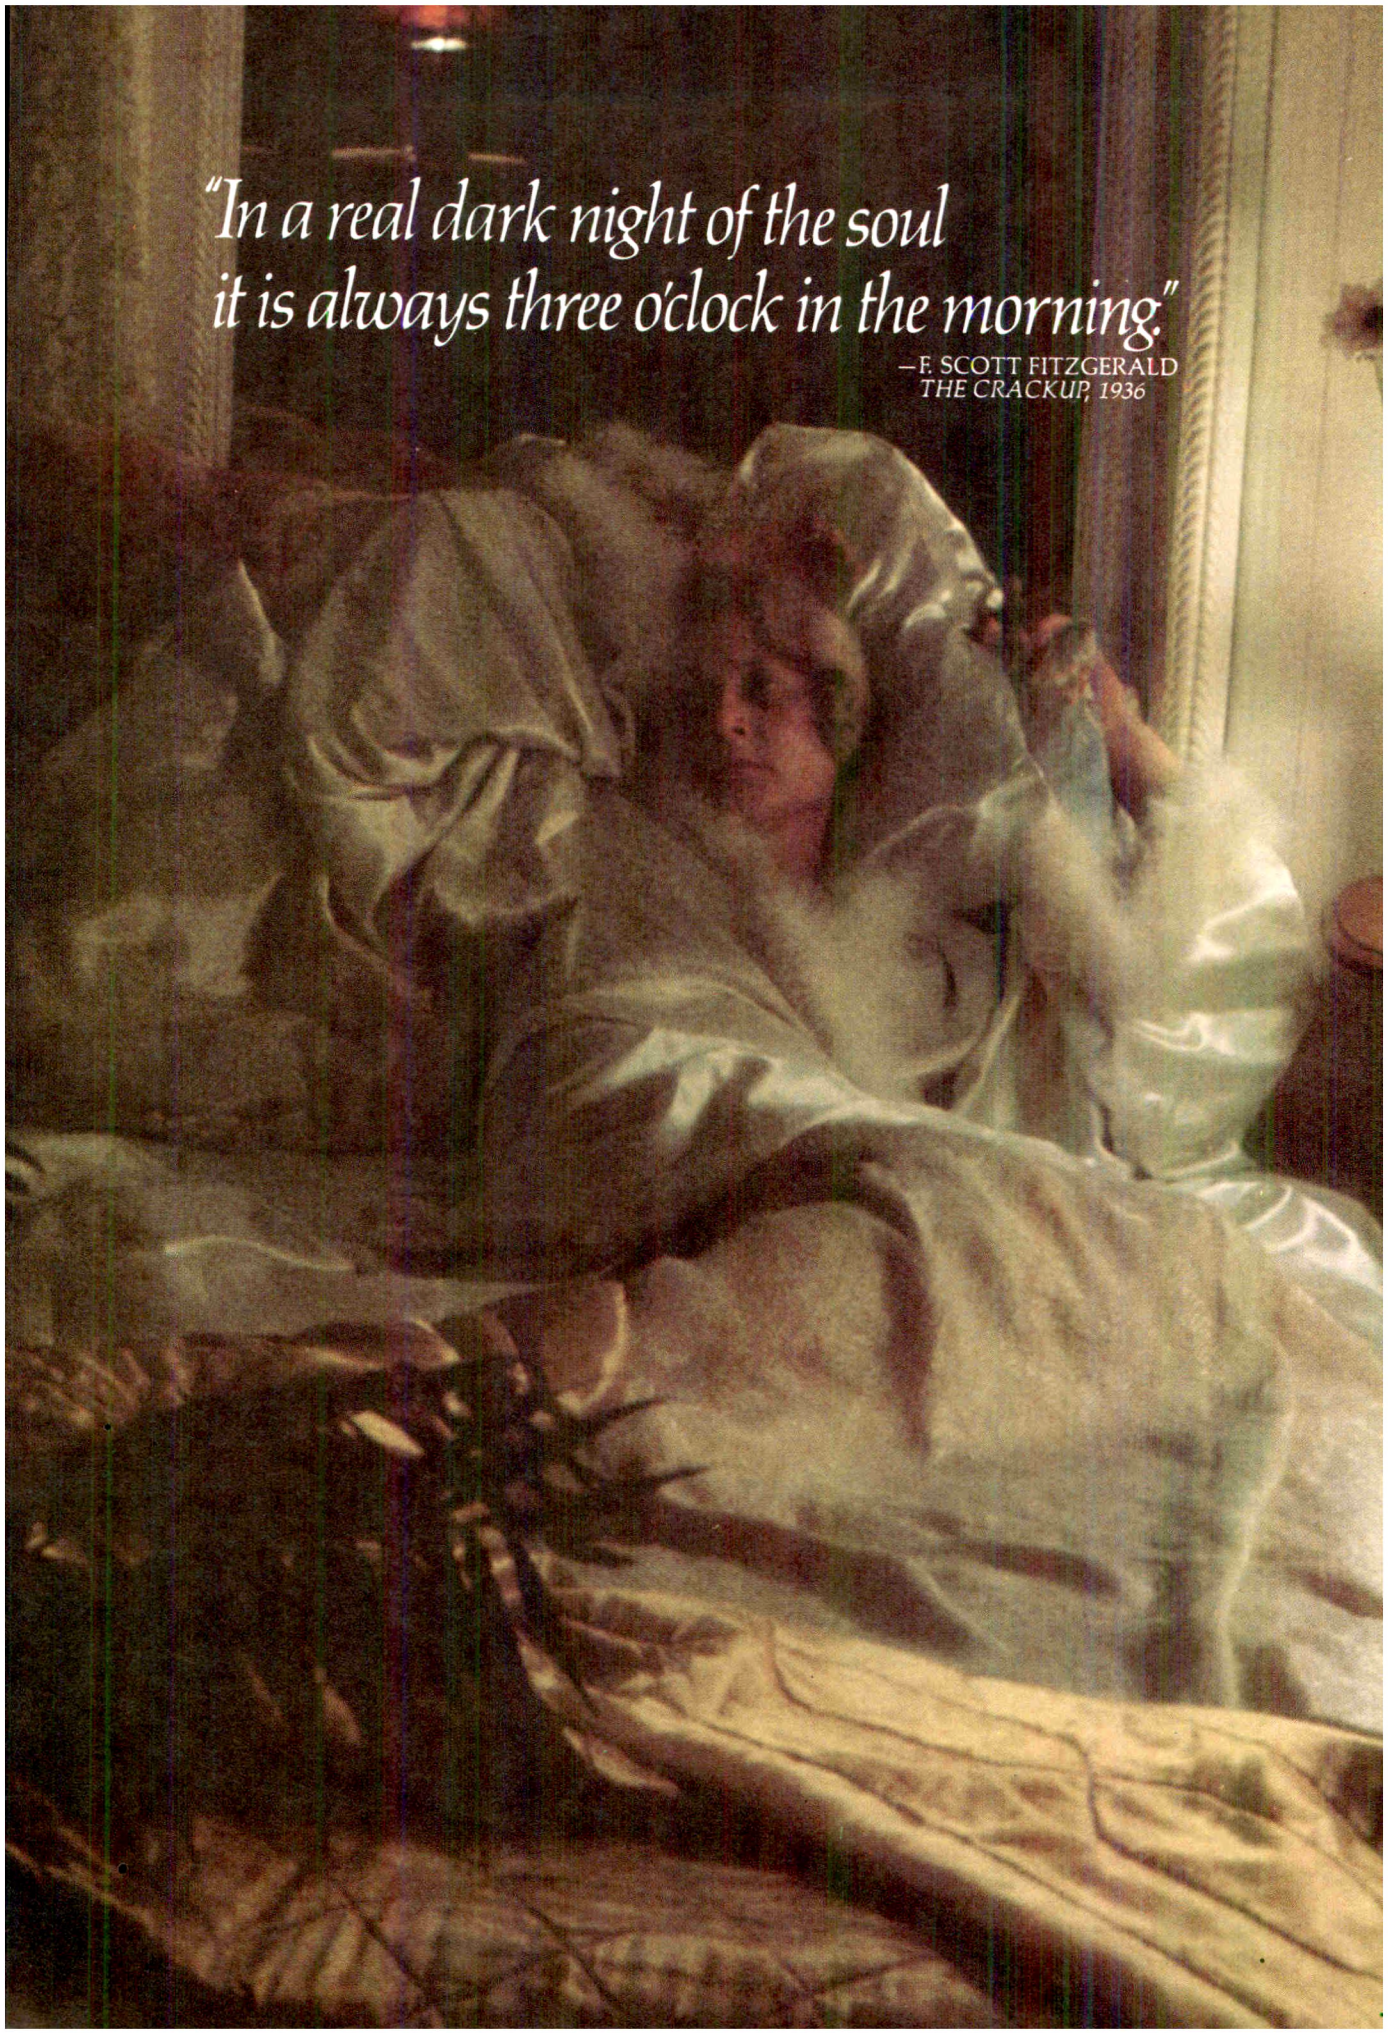
ALBERTA, CANADA PSYCHIATRISTS

ARE YOU A CANADIAN INTERESTED IN RETURNING?

As Canada's fourth largest province, Alberta (1,954,500 population) is experiencing a phase of economic growth primarily based on its energy resources. Its residents enjoy a vigorous cultural life and a high standard of facilities and services. The development of the Health Sciences Centre (Phase I cost is U.S. $85,000,000) will make its capital city, Edmonton, a major centre in health care research.

Rapid expansion of Forensic Psychiatric Services in Alberta and the erection of a new Forensic Facility at Alberta Hospital, Edmonton, have resulted in the creation of three new positions. The psychiatrists will be expected to allot their time to work with Alberta Hospital Forensic Services and the Federal and Provincial Correctional Institutions, which are all in close proximity. If the successful appointees desire they may conduct sessions at the Forensic Out-Patient Service located in downtown Edmonton.

In addition, general and specialty positions exist in various large and small urban locations with Alberta Mental Health Services. Most are team-oriented, community or part time community positions backed by excellent medical and paramedical staff and services.



Basic requirement is eligibility to practice medicine in Alberta. Advanced training is desirable and recognized in our salary schedule.

Salary range is from U.S. $25,000 to U.S. $48,430, plus duty roster pay. Financial arrangements include removal expenses. (Exchange calculated as of December 13, 1978.)

For further information, call Dr. David R. Cornish (collect) at (403) 973-2438 OR write, in confidence, to:

THE CRACKUP, 1936

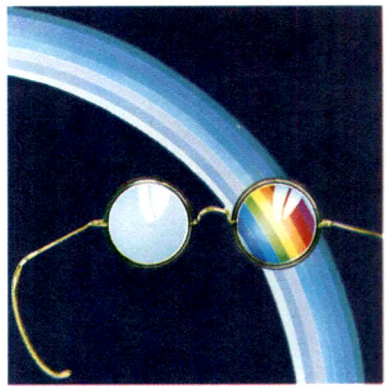
Insomnia
a shade of blue that often accompanies depression

And, in anxiety/depression, Adapin® (doxepin HCl) often helps restore disturbed sleep patterns, such as early morning wakening, with a single daily dose at bedtime. Adapin quickly relieves the patient's anxiety, gradually brightens his mood and outlook, with optimal antidepressant response usually evident within two to three weeks.

Brief Summary of Prescribing Information
ADAPIN® (doxepin HCl) Capsules

Indications—Relief of symptoms of anxiety and depression.

Contraindications—Glaucoma, tendency toward urinary retention, or hypersensitivity to doxepin.



Warnings—Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.
Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.
In patients who may use alcohol excessively potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions—Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

Adverse Reactions—Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.
Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as heating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, claustrophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration—In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at one time without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.
Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied—Each capsule contains doxepin, as the hydrochloride: 10 mg, 25 mg, 50 mg and 100 mg capsules in bottles of 100 and 1000.
For complete prescribing information please see package insert or PDR.

Prescribing Information for

Lidone™ (molindone hydrochloride)

DESCRIPTION — LIDONE (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

LIDONE is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4(5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

ACTIONS — LIDONE (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditional response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, LIDONE antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, LIDONE exerts its effect on the ascending reticular activating system.

Human metabolic studies show LIDONE (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24 to 36 hours. There are 36 recognized metabolites with less than 2 to 3% unmetabolized LIDONE being excreted in urine and feces.

INDICATIONS — LIDONE (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS — LIDONE (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS

Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats Oral Dose —
20 mg/kg/day — 10 days, no adverse effect
40 mg/kg/day — 10 days, no adverse effect

Pregnant Mice Oral Dose —
20 mg/kg/day — 10 days, slight increase resorptions
40 mg/kg/day — 10 days, slight increase resorptions

Pregnant Rabbits Oral Dose —
5 mg/kg/day — 12 days, no adverse effect
10 mg/kg/day — 12 days, no adverse effect
20 mg/kg/day — 12 days, no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of LIDONE (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of LIDONE (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

PRECAUTIONS — Some patients receiving LIDONE (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving LIDONE. Caution should be exercised where increased activity may be harmful.

LIDONE does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, convulsive seizures have been reported in a few instances.

LIDONE has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS

CNS Effects — The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological Extrapyramidal Reactions — Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia — Motor restlessness may occur early.

Parkinson Syndrome — Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome — Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System — Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological — There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with LIDONE may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects — Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Lactation associated with LIDONE therapy has not been reported. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with LIDONE.

Cardiovascular — Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological — Lens opacities and pigmentary retinopathy have not been reported where patients have received LIDONE (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with LIDONE.

Skin — Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with LIDONE usage alone.

LIDONE (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when LIDONE is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia — Although rarely reported with LIDONE (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movement may be involuntary movements of extrer

There is no known effective treatment dyskinesia; antiparkinsonism agents u not alleviate the symptoms of this syndr suggested that all antipsychotic agents b tinued if these symptoms appear. Should essary to reinstitute treatment, or inc dosage of the agent, or switch to a diffe psychotic agent, the syndrome may be m has been reported that fine vermicular m of the tongue may be an early sign of the and if the medication is stopped at that syndrome may not develop.

DOSAGE AND ADMINISTRATION — I maintenance doses of LIDONE (molindor chloride) should be individualized.

Initial Dosage Schedule

The usual starting dosage is 50 to 75 mg
- Increase to 100 mg/day in three or f
- Based on severity of symptomatolog may be titrated up or down dependi dividual patient response.
- An increase to 225 mg/day may be re patients with severe symptomatolog
- Some chronic, treatment-resistant may require up to 400 mg/day; (how long-term safety of 400 mg/day has established).

Elderly or debilitated patients should be st lower dosage.

Maintenance Dosage Schedule

1. Mild — 5 mg to 15 mg three or four tim
2. Moderate — 10 mg to 25 mg three or fou day.
3. Severe — 225 mg/day may be required.

Dosage may be administered once a day.

DRUG INTERACTIONS — Potentiation administered concurrently with LIDONE done hydrochloride) has not been reporte tionally, animal studies have not shown i toxicity when LIDONE is given concurren representative members of three classes (i.e., barbiturates, chloral hydrate and ant son drugs).

MANAGEMENT OF OVERDOSAGE — matic, supportive therapy should be the r

Gastric lavage is indicated for the redu absorption of LIDONE (molindone hydroc which is freely soluble in water.

Since the adsorption of LIDONE (molinc drochloride) by activated charcoal has n determined, the use of this antidote must sidered of theoretical value.

Emesis in a comatose patient is contrain Additionally, while the emetic ef apomorphine is blocked by LIDONE in anim blocking effect has not been determi humans.

A significant increase in the rate of rer unmetabolized LIDONE from the body by diuresis, peritoneal or renal dialysis woul expected. (Only 2% of a single ingested LIDONE is excreted unmetabolized in the However, poor response of the patient may use of these procedures.

While the use of laxatives or enemas m based on general principles, the amount metabolized LIDONE in feces is less than trapyramidal symptoms have responded to of diphenhydramine (Benadryl*) and th thetic anticholinergic antiparkinson agen Artane*, Cogentin*, Akineton*).

Helps weather
the manic storm

maintenance therapy with Eskalith® 300 mg capsules and of lithium carbonate

In manic-depressive patients with a history of mania, 'Eskalith'

prevents or diminishes the intensity of future episodes

can increase the intervals between episodes

helps patients function within normal limits

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

WARNING
Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

Indications: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in manic-depressive patients with a history of mania.

Warnings: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, sodium depletion, or to patients receiving diuretics.

Lithium therapy has been reported in some cases to be associated with morphologic changes in the kidneys.

Caution patient and family to watch for diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness as signs of lithium toxicity, and to discontinue therapy and contact a physician should they occur. Patients receiving combined therapy with lithium and an antipsychotic should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery).

Lithium should not be used in pregnancy, especially during the first trimester, unless potential benefits outweigh possible hazards.

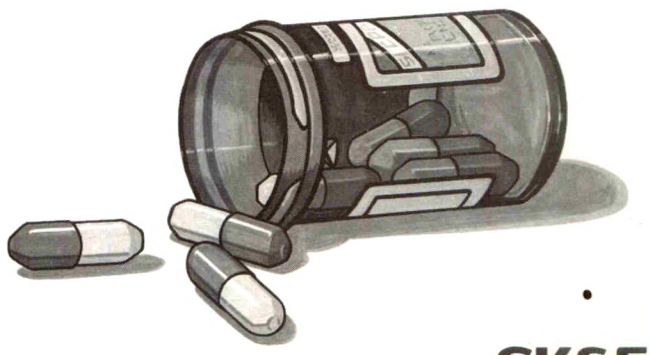
Not recommended for children under 12.

Precautions: Lithium tolerance is greater during the acute manic phase and decreases when manic symptoms subside.

Lithium therapy may lead to sodium depletion. Normal diet (including salt) and adequate fluid intake (2500-3000 ml.) must be maintained, at least during initial stabilization period. Protracted sweating or diarrhea can decrease tolerance; in such cases, administer supplemental fluid and salt.

Sweating, diarrhea, and concomitant infection with elevated temperatures may require temporary reduction or cessation of dosage.

Adverse Reactions: Mild to moderate toxic reactions may occur at serum lithium levels from 1.5 to 2.5 mEq./l., and moderate to severe reactions at levels from 2.0 to 2.5 mEq./l. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and persist. Transient and mild nausea and general discomfort also appear during initial therapy. These effects usually subside with continued treatment or temporary reduction or cessation of dosage. If persistent, discontinue dosage.



Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of toxicity and may occur at levels below 2.0 mEq./l. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum levels above 3.0 mEq./l. may produce a complex clinical picture, involving multiple organs and systems. Serum levels should not exceed 2.0 mEq./l. during acute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: **Neuromuscular**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; **Central Nervous System**—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea; **Genitourinary**—albuminuria, oliguria, polyuria, glycosuria; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; **Autonomic**—blurred vision, dry mouth; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; **EEG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.

Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.

How Supplied: 300 mg. capsules in bottles of 100.

INSOMNIA

that continues for up to two weeks outlasts most hypnotics.

ONLY **DALMANE**® (flurazepam HCl) C-IV

›rovides significant efficacy for chronic insomniacs from the first through 28 consecutive nights of investigation.

ective investigations prove the continuing efficacy of mane 30 mg *h.s.* during a 4-week medication period.[1-3] ontrast, a recently published sleep laboratory study orted the absence of a statistically significant hypnotic ct for chloral hydrate (1 Gm), ethchlorvynol (500 mg),* ethimide (500 mg), methaqualone (250 and 400 mg) secobarbital (100 mg) at the end of two weeks of inistration.[4] Another study demonstrated that total e time in insomniacs receiving pentobarbital (100 mg) rned to premedication baseline levels within 14 nights.[2] ecause insomnia is often transient, the prolonged inistration of Dalmane is seldom necessary. If therapy st be extended, periodic blood counts and liver and ney function tests should be performed.

her recently published study showed that ethchlorvynol (500 mg) did esult in a statistically significant reduction of sleep latency, minutes ake time after sleep onset, number of nighttime awakenings and unt of wakefulness at medication nights 1-3 or at medication ts 12-14.[5]

Less risk of accidental or purposeful overdosage with Dalmane (flurazepam HCl)

"Flurazepam has a higher therapeutic index (lethal: hypnotic dose) than the other sedative-hypnotics; thus, there is less risk of accidental overdosage or potential use as a suicide agent."[6]

As with all medications of its type, Dalmane should be administered with caution to severely depressed patients or those with any evidence of latent depression. Protective measures should be taken for patients with suicidal tendencies.

Please see following page for a summary of product information.

ROCHE

FOR AN UNSURPASSED RECORD OF EFFECTIVENESS AND SAFETY

DALMANE®
(flurazepam HCl) C IV

30-MG AND 15-MG CAPSULES

One 30-mg capsule *h.s.*— usual adult dosage
(15 mg may suffice in some patients).
One 15-mg capsule *h.s.*— recommended dosage for elderly or debilitated patients.

Before prescribing Dalmane (flurazepam HCl), please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated, limit dosage to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients.
Elderly or debilitated patients: 15 mg initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

Tranxene® (CLORAZEPATE DIPOTASSIUM) 4306CB

CAPSULES,
SINGLE DOSE TABLETS

Brief Summary

ACTIONS — Pharmacologically, clorazepate dipotassium has the characteristics of the benzodiazepines. It has depressant effects on the central nervous system. The primary metabolite, nordiazepam, quickly appears in the blood stream. The serum half-life is about 2 days. The drug is metabolized in the liver and excreted primarily in the urine. (See CLINICAL PHARMACOLOGY section.)

INDICATIONS — TRANXENE is indicated for the symptomatic relief of anxiety associated with anxiety neurosis, in other psychoneuroses in which anxiety symptoms are prominent features, and as an adjunct in disease states in which anxiety is manifested.

TRANXENE is indicated for the symptomatic relief of acute alcohol withdrawal.

The effectiveness of TRANXENE in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should reassess periodically the usefulness of the drug for the individual patient.

CONTRAINDICATIONS — TRANXENE is contraindicated in patients with a known hypersensitivity to the drug, and in those with acute narrow angle glaucoma.

WARNINGS — TRANXENE is not recommended for use in depressive neuroses or in psychotic reactions.

Patients on TRANXENE should be cautioned against engaging in hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles.

Since TRANXENE has a central nervous system depressant effect, patients should be advised against the simultaneous use of other CNS-depressant drugs, and cautioned that the effects of alcohol may be increased.

Because of the lack of sufficient clinical experience, TRANXENE is not recommended for use in patients less than 18 years of age.

Physical and Psychological Dependence:

Withdrawal symptoms (similar in character to those noted with barbiturates and alcohol) have occurred following abrupt discontinuance of clorazepate. Symptoms of nervousness, insomnia, irritability, diarrhea, muscle aches and memory impairment have followed abrupt withdrawal after long-term use of high dosage.

Caution should be observed in patients who are considered to have a psychological potential for drug dependence.

Evidence of drug dependence has been observed in dogs and rabbits which was characterized by convulsive seizures when the drug was abruptly withdrawn or the dose was reduced; the syndrome in dogs could be abolished by administration of clorazepate.

Usage in Pregnancy:

An increased risk of congenital malformations associated with the use of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) during the first trimester of pregnancy has been suggested in several studies. TRANXENE, a benzodiazepine derivative, has not been studied adequately to determine whether it, too, may be associated with an increased risk of fetal abnormality. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. The possibility that a woman of childbearing potential may be pregnant at the time of institution of therapy should be considered. Patients should be advised that if they become pregnant during therapy or intend to become pregnant they should communicate with their physician about the desirability of discontinuing the drug.

Usage during Lactation:

TRANXENE should not be given to nursing mothers since it has been reported that nordiazepam is excreted in human breast milk.

PRECAUTIONS — In those patients in which a degree of depression accompanies the anxiety, suicidal tendencies may be present and protective measures may be required. The least amount of drug that is feasible should be available to the patient.

Patients on TRANXENE for prolonged periods should have blood counts and liver function tests periodically. The usual precautions in treating patients with impaired renal or hepatic function should also be observed.

In elderly or debilitated patients, the initial dose should be small, and increments should be made gradually, in accordance with the response of the patient, to preclude ataxia or excessive sedation.

ADVERSE REACTIONS — The side effect most frequently reported was drowsiness. Less commonly reported (in descending order of occurrence) were: dizziness, various gastrointestinal complaints, nervousness, blurred vision, dry mouth, headache, and mental confusion. Other side effects included insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression and slurred speech.

There have been reports of abnormal liver and kidney function tests and of decrease in hematocrit.

Decrease in systolic blood pressure has been observed.

DOSAGE AND ADMINISTRATION

For the symptomatic relief of anxiety:

TRANXENE is administered orally. The capsules may be given in divided doses. The usual daily dose is 30 mg. The dose should be adjusted gradually within the range of 15 to 60 mg. daily in accordance with the response of the patient. In elderly or debilitated patients it is advisable to initiate treatment at a daily dose of 7.5 to 15 mg.

TRANXENE capsules may also be administered as a single dose daily at bedtime; the recommended initial dose is 15 mg. After the initial dose, the response of the patient may require adjustment of subsequent dosage. Lower doses may be indicated in the elderly patient. Drowsiness may occur at the initiation of treatment and with dosage increment.

TRANXENE-SD tablets (22.5 mg.) may be administered as a single dose every 24 hours. This tablet is intended as an alternate dosage form for the convenience of patients stabilized on a dose of 7.5 mg. capsules three times a day. TRANXENE-SD tablets should not be used to initiate therapy.

TRANXENE-SD HALF STRENGTH tablets (11.25 mg.) may be administered as a single dose every 24 hours.

For the symptomatic relief of acute alcohol withdrawal:

Recommended schedule: 1st 24 hours, 30 mg. TRANXENE initially, followed by 30 to 60 mg. in divided doses; 2nd 24 hours, 45 to 90 mg. in divided doses; 3rd 24 hours, 22.5 to 45 mg. in divided doses; 4th day, 15 to 30 mg. in divided doses. Thereafter gradually reduce to 7.5 to 15 mg. daily, and discontinue as soon as condition is stable. Maximum daily dose is 90 mg. Avoid excessive reductions in total drug on successive days.

DRUG INTERACTIONS — If TRANXENE is to be combined with other drugs acting on the central nervous system, careful consideration should be given to the pharmacology of the agents to be employed. Animal experience indicates that TRANXENE prolongs the sleeping time after hexobarbital or after ethyl alcohol, increases the inhibitory effects of chlorpromazine, but does not exhibit monoamine oxidase inhibition. Clinical studies have shown increased sedation with concurrent hypnotic medications. The actions of the benzodiazepines may be potentiated by barbiturates, narcotics, phenothiazines, monoamine oxidase inhibitors or other antidepressants.

If TRANXENE is used to treat anxiety associated with somatic disease states, careful attention must be paid to possible drug interaction with concomitant medication.

MANAGEMENT OF OVERDOSAGE — Overdosage is usually manifested by varying degrees of CNS depression ranging from slight sedation to coma. As in the management of overdosage with any drug, it should be borne in mind that multiple agents may have been taken.

There are no specific antidotes for the benzodiazepines. The treatment of overdosage should consist of the general measures employed in the management of overdosage of any CNS depressant. Gastric evacuation either by the induction of emesis, lavage, or both, should be performed immediately. General supportive care, including frequent monitoring of the vital signs and close observation of the patient, is indicated. Hypotension, though rarely reported, may occur with large overdoses. In such cases the use of agents such as Levophed® (levarterenol) or Aramine® (metaraminol) should be considered.

While reports indicate that individuals have survived overdoses of TRANXENE (clorazepate dipotassium) as high as 450 to 675 mg., these doses are not necessarily an accurate indication of the amount of drug absorbed since the time interval between ingestion and the institution of treatment was not always known. Sedation in varying degrees was the most common physiological manifestation of TRANXENE overdosage. Deep coma when it occurred was usually associated with the ingestion of other drugs in addition to TRANXENE.

CLINICAL PHARMACOLOGY — Studies in healthy men have shown that TRANXENE has depressant effects on the central nervous system. Prolonged administration of single daily doses as high as 120 mg. was without toxic effects. Abrupt cessation of high doses was followed in some patients by nervousness, insomnia, irritability, diarrhea, muscle aches, or memory impairment.

Absorption — Excretion:

After oral administration of TRANXENE, there is essentially no circulating parent drug. Nordiazepam, its primary metabolite, quickly appears in the blood stream. In 2 volunteers given 15 mg. (50 μC) of ^{14}C-TRANXENE, about 80% was recovered in the urine and feces within 10 days. Excretion was primarily in the urine with about 1% excreted per day on day 10.

HOW SUPPLIED — TRANXENE (clorazepate dipotassium) is supplied as capsules in three dosage strengths:

3.75 mg. capsules (gray with white cap) in bottles of 100 (NDC 0074-3417-13) and 500 (NDC 0074-3417-53). Also available in ABBO-PAC® unit dose packages of 100 capsules (NDC 0074-3417-11).

7.5 mg. capsules (gray with maroon cap) in bottles of 30 (NDC 0074-3418-30), 100 (NDC 0074-3418-13) and 500 (NDC 0074-3418-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3418-11).

15 mg. capsules (all gray) in bottles of 100 (NDC 0074-3419-13) and 500 (NDC 0074-3419-53). Also available in ABBO-PAC unit dose packages of 100 capsules (NDC 0074-3419-11).

TRANXENE-SD single dose tablets are supplied in two dosage strengths:

TRANXENE-SD 22.5 mg. tablets (tan-colored) in bottles of 100 (NDC 0074-2997-13).

TRANXENE-SD HALF STRENGTH 11.25 mg. tablets (blue-colored) in bottles of 30 (NDC 0074-2699-30) and 100 (NDC 0074-2699-13).

8083271

Not drowsy by day, yet anxiety controlled

Troublesome drowsiness uncommon. Tranxene lets you manage anxiety in most patients without problem sedation. Any initial drowsiness is usually transient. By avoiding excessive sedation, Tranxene helps you calm patients without compromising their capacities.*

CAPSULES: 3.75, 7.5, 15 mg.
TABLETS: 11.25, 22.5 mg.

CHLORPROMAZINE

Tablets:
50 and 100 mg
of the HCl

Back to work. She went into the hospital with a psychiatric emergency but left more like herself—delusions, hallucinations, and other psychotic target symptoms effectively managed with 'Thorazine'. And 'Thorazine' maintenance can help keep her out of the hospital in the future.

From initial psychiatric emergency through maintenance treatment, 'Thorazine' offers effective antipsychotic therapy with 18 convenient dosage forms and strengths. This means you can precisely tailor dosage to the individual patient's needs—increasing or decreasing as the situation demands.

'Thorazine'. The most widely tested and highly flexible antipsychotic available today.

Helps return psychotic patients to reality

efore prescribing, see complete prescribing nformation in SK&F literature or PDR. The llowing is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of manifestations of psychotic disorders. For control of the manifestations of manic-depressive illness (manic phase).

Probably effective: For the control of moderate to severe agitation, hyperactivity or aggressiveness in disturbed children.

Possibly effective: For control of excessive anxiety, tension and agitation as seen in neuroses.

Final classification of the less-than-effective indications requires further investigation.

ontraindications: Comatose states, presence of rge amounts of C.N.S. depressants, or bone arrow depression.

Warnings: The possibility of extrapyramidal eactions from 'Thorazine' may confuse the agnosis of Reye's syndrome or other encephapathy. Therefore, avoid use in children or olescents with suspected Reye's syndrome.

oid using in patients hypersensitive (e.g., blood scrasia, jaundice) to any phenothiazine. Caution ients about activities requiring alertness (e.g., rating vehicles or machinery) especially during first few days' therapy. Avoid concomitant with alcohol. May counteract antihypertenseffect of guanethidine and related compounds.

n pregnancy only when essential. There are ted instances of jaundice or prolonged extraidal signs in newborn whose mothers had ed chlorpromazine.

tions: Use cautiously in persons with vascular, liver or chronic respiratory , or with acute respiratory infections. Due h reflex suppression, aspiration of vomitus ble. May prolong or intensify the action depressants, organophosphorus insecticat, atropine and related drugs. (Reduce f concomitant C.N.S. depressants.) Anti-

convulsant action of barbiturates is not intensified. Antiemetic effect may mask signs of toxic drug overdosage or obscure diagnosis of conditions such as intestinal obstruction, brain tumor, and Reye's syndrome (see Warnings). Discontinue high-dose, long-term therapy gradually.

Patients on long-term therapy, especially high doses, should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, cholestatic jaundice, agranulocytosis, eosinophilia, leukopenia, hemolytic anemia, thrombocytopenic purpura and pancytopenia; postural hypotension, tachycardia, fainting, dizziness and, occasionally, a shock-like condition; reversal of epinephrine effects; EKG changes have been reported, but relationship to myocardial damage is not confirmed; neuromuscular (extrapyramidal) reactions; pseudoparkinsonism, motor restlessness, dystonias, persistent tardive dyskinesia, hyperreflexia in the newborn; psychotic symptoms, catatonic-like states, cerebral edema; convulsive seizures; abnormality of the cerebrospinal fluid proteins; urticarial reactions and photosensitivity, exfoliative dermatitis, contact dermatitis; lactation and breast engorgement (in females on large doses), false positive pregnancy tests, amenorrhea, gynecomastia; hyperglycemia, hypoglycemia, glycosuria; dry mouth, nasal congestion, constipation, adynamic ileus, urinary retention, miosis, mydriasis; after prolonged substantial doses, skin pigmentation, epithelial keratopathy, lenticular and corneal deposits and pigmentary retinopathy, visual impairment; mild fever (after large I.M. dosage); hyperpyrexia; increased appetite and weight; a systemic lupus erythematosus-like syndrome; peripheral edema.

NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 10 mg., 25 mg., 50 mg., 100 mg. and 200 mg., in bottles of 100; Single Unit Packages of 100 (intended for institutional use only).

Spansule® capsules, 30 mg., 75 mg., 150 mg., 200 mg. and 300 mg., in bottles of 50; in Single Unit Packages of 100 (intended for institutional use only).

Injection, 25 mg./ml.; Syrup, 10 mg./5 ml.; Suppositories, 25 mg. and 100 mg.

Concentrate (intended for institutional use only), 30 mg./ml. and 100 mg./ml.

Announces

REOPENING OF APPLICATIONS FOR THE APA/NIMH MINORITY* FELLOWSHIP PROGRAM

This program, supported by NIMH funding, has provided partial stipend assistance and support for participation in APA meetings. The objectives of the program are to increase the number of minority group psychiatrists, to provide educational enrichment and stimulate interest in pursuing training in those areas in which minority groups are especially underrepresented.

Applications** are being accepted through March 15, 1979, for residencies beginning in July 1979. Applicants must be US citizens and must have graduated from a U.S. medical school or possess the ECFMG certificate.

Information is available from:

Jeanne Spurlock, M.D.
Office of Minority Affairs
American Psychiatric Association
1700 18th Street, N.W.
Washington, D.C. 20009
Telephone (202) 797-4875
or 797-4878

* including but not limited to: American Indians, Asian Americans, Black Americans and Spanish-Speaking Americans.

** A limited number of stipends are subject to the availability of funds.

The American Journal of Psychiatry is published by the American Psychiatric Association 13 times a year (monthly, plus a second issue in April devoted in 1979 to depression and alcoholism). Editorial office: 1700 Eighteenth Street, N.W., Washington, D.C. 20009; telephone (202) 797-4918.

Subscriptions: U.S. $18.00 per year, Canada and foreign $26.00; single issues: U.S. $2.25, Canada and foreign $2.90.

Business communications and changes of address from APA members should be directed to the Division of Membership Services and Studies. Communications from nonmember subscribers should be directed to the Circulation Department, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009.

THE AMERICAN PSYCHIATRIC ASSOCIATION
1700 Eighteenth Street, N.W., Washington, D.C. 20009

OFFICERS 1978–1979

President: JULES MASSERMAN
President-Elect: ALAN A. STONE
Vice-President: DONALD G. LANGSLEY
Vice-President: LEWIS L. ROBBINS
Secretary: H. KEITH H. BRODIE
Treasurer: CHARLES B. WILKINSON

ASSEMBLY OF DISTRICT BRANCHES

Speaker: ROBERT J. CAMPBELL
Speaker-Elect: ROBERT O. PASNAU
Recorder: MELVIN M. LIPSETT

MEDICAL DIRECTOR'S OFFICE

Medical Director: MELVIN SABSHIN
Deputy Medical Directors: DONALD W. HAMMERSLEY, CAROLYN B. ROBINOWITZ, JEANNE SPURLOCK, HENRY H. WORK

BOARD OF TRUSTEES

For Three Years: JACK WEINBERG, JOHN A. TALBOTT, HENRY B. BRACKIN, JR., GENE USDIN

For Two Years: ROBERT W. GIBSON, ABRAM M. HOSTETTE[illegible], ROBERT A. MOORE, MARY ANN BARTUSIS

For One Year: JUDD MARMOR, BEN W. FEATHER, WILLIAM B. SPRIEGE[illegible], DAVID STARRETT, NANCY C. A. ROESKE

Consultant: MAE MCMILLAN
Residents' Representative: ROBERT MARIN
APA-NIMH Minority Fellow Representative: PATRICIA NEWTON

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, and are not being considered for publication elsewhere. Papers with multiple authors are reviewed with the assumption that all authors have approved them.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. All submissions must be accompanied by a cover letter *signed by all authors* and using the following wording:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. The cover letter in such cases should contain the following wording and should be signed by all authors:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 2–3 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by the appropriate cover letter, including the copyright transfer statement, will not be reviewed until such a statement is received.

Authors will be notified as soon as possible of the receipt of their paper; at this time, the paper will be assigned a number that must be included in all further correspondence. It is imperative that authors of papers under consideration notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in *final form*, i.e., are ready for review. Authors must *not* submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions, and not all papers can be published in the *Journal*. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; this number must appear in any further communications about the paper. The copyright transfer statement described above must accompany annual meeting papers submitted for review.

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent, including references, tables, and figures (about 15 manuscript pages). Brief Communications—2,500 words or equivalent (about 10 manuscript pages). Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures can be used in this section). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 25 double-spaced pages (about 7,500 words) and should have no more than 100 references. All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures or references, etc. Single case reports will not be accepted as regular articles or Brief Communications; these papers should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and *no figures*) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular or Brief Communication length (a "prompt publication policy" is automatically in effect for Clinical and Research Reports). These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality, and authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed *double-spaced* throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review or listing may be sent directly to the Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. Book reviews are usually solicited by the editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer. Reviews are usually less than 500 words long, seldom contain references, and will be edited.

TYPING AND ARRANGING THE PAPER

All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) *nonerasable* bond paper. All parts of the manuscript, including case reports, quotations, references, and tables, must be double-spaced throughout. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Please include degrees (other than honorary or undergraduate) after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. The authors' position titles and affiliations should be given in a paragraph using complete sentences. A full address is necessary only for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a sepa rate paragraph on the title page. Grant support should in clude the full name of the granting agency as well as the grar number. Individual acknowledgments should be as brief a possible. Acknowledgments of companies that supplie drugs are used only in the case of experimental drugs c those unavailable in this country.

Other requirements. The number of words, tables, and fig ures should appear in the upper right corner and a phon number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articl and Brief Communications (no précis is used in the Clinic and Research Reports section). The précis should be a sing paragraph using complete, connected sentences, acti verbs, and the third person. In most cases, the précis r places a summary.

Text

Headings and subheadings should be inserted at reaso able intervals in all types of papers. Footnotes to text mate al should be typed on a separate page at the end of the man script. Summaries are rarely desirable, although a fin "Comment" or "Conclusions" section may be used. Th body of the paper should be written in the active voice ar first person where appropriate.

Statistics. Authors should be sure that statistics used a both necessary and appropriate. Statistical tests should described and a reference citation given if the tests are n generally known. It is not sufficient to say "differences b tween the groups were significant." In cases of lengthy co plicated analyses, the authors may summarize results a indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those f metric units) should be explained the first time they are use Idiosyncratic abbreviations should be avoided: overuse abbreviations may hinder rather than facilitate readability

Drugs. Generic rather than trade names of drugs should used; trade names may be given parenthetically if necessa

Units of measurement. All measurements should be metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent ma rial; a complete review of the literature is rarely desirab *Accuracy of citation is the author's responsibility.* Ref ences should conform exactly to the original spelling, cents, punctuation, etc. Authors should be sure that all ref ences listed have been cited in text; no bibliographies can used.

References are numbered and listed by their order of pearance in text; the text citation is followed by the app priate reference number in parentheses. Do *not* arrange list alphabetically.

Personal communications, unpublished manuscripts, m uscripts submitted but not yet accepted, and similar unp lished items should not appear in the reference list. Such tations may be noted in text or in a footnote. It is the thor's responsibility to obtain permission to refer to anot individual's unpublished observations. Manuscripts that actually "in press" may be cited as such in the reference l the name of the journal must be included.

Type references in the style shown below and on the r page, double-spaced *throughout* (not just a line betw references). List up to three authors; designate one or m authors past the third "et al." Abbreviations of jou names should conform to the style used in *Index Medic* journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxf University Press, 1966, p 26

2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
3. Gold PW, Goodwin FK: Urinary free cortisol in depression and mania. Presented at the 130th annual meeting of the American Psychiatric Association, Toronto, Ont, Canada, May 2–6, 1977
4. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise title.

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints with one photocopy attached to each manuscript copy. The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information available in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit use for educational purposes or of an author who wishes to reprint his/her own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article. Reprint orders from others should be directed to the APA Publications Services Division; inclusion of a letter of permission from the senior author and a brief statement of the intended use of the reprints will expedite the processing of such requests.

The April 1979 issue of

The American Journal of Psychiatry

will feature

- **Platelet Monoamine Oxidase Activity in Schizophrenia: A Review of the Data**

  By Richard Jed Wyatt, Steven G. Potkin, and Dennis L. Murphy

Hallucinations... delusions... thought disorders... controlled

Navane (thiothixene) rapidly controls hallucinations as well as the agitation and hostility patterns they frequently generate.

Rapid control of psychotic symptoms on admission

Navane provides effective, rapid control of the major symptoms of psychosis including hallucinations, delusions, agitation, hostility, and thought disorders.[1-5] Navane promotes rapid progress, usually without the over-sedation or cardiovascular problems that can impede the therapeutic course.

Continued long-term improvement

Because Navane provides long-term outpatient control of psychotic symptoms, it can enable many patients to function effectively at home and on the job and to adjust rapidly to the community.[6]

Effectiveness rarely compromised by adverse reactions

Navane allows patients to remain alert and active, seldom causing oversedation or drowsiness.[7] Hypotension and other cardiovascular reactions[5,6,8] are seldom reported and the occurrence of unpleasant anticholinergic side effects such as dry mouth or constipation is rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled through dosage adjustments or antiparkinson agents.

Rapid control
Long-term improvement

Navane®

(thiothixene) (thiothixene HCl)

Capsules 1 mg., 2 mg., 5 mg., 10 mg., 20 mg. Concentrate 5 mg./ml. Intramuscular 2 mg./ml.

For prescribing information, including adverse reactions and contraindications, please see following page of this advertisement.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules 1 mg, 2 mg, 5 mg, 10 mg, 20 mg
(thiothixene hydrochloride) Concentrate: 5 mg/ml,
Intramuscular: 2 mg/ml

Contraindications. Navane is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*—Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children—The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration—As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution—For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage. Dosage recommendations for Navane Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate—In milder conditions, an initial dose of 2 mg three times daily. If indicated, subsequent increase to 15 mg/day total daily dose is usually effective.

In more severe conditions, an initial dose of 5 mg two to four times daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, and coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral or Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor effect of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Picrotoxin or pentylenetetrazol should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100 and 1,000. Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100 and 500.

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10. Each ml contains thiothixene hydrochloride equivalent to 2 mg thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, propyl gallate 0.02% w/v.
